CONTRIBUTORS

FRANK E. ADAIR, A.B., M.D., D.Sc. (Hon.), F.A.C.S.

[Paget's Disease of the Nipple, Sarcoma of the Breast, Traumatic Fat Necrosis, Tuberculous and Syphilis of the Breast]

Associate Professor of Clinical Surgery, Cornell University Medical School, Attending Surgeon and Executive Officer, Memorial Hospital New York City, Chairman Committee on Treatment of Malignant Diseases of the American College of Surgeons, President, American Cancer Society

WILLIAM E. ADAMS, R.S., M.D., F.A.C.S.

[Inflammations of the Chest Wall, etc.]

Associate Professor of Surgery, University of Chicago School of Medicine, Attending Surgeon and Chief Thoracic Surgeon, University of Chicago Clinics, Consulting Thoracic Surgeon, Provident Hospital, Chicago

ALFRED W. ADSON, B.Sc., M.A., M.D., M.S. (in Surgery), F.A.C.S.

[Glossopharyngeal Neuralgia, Sciatica, Cervical Rib]

Professor of Neurosurgery, the Mayo Foundation, Graduate School, University of Minnesota, Chief Neurosurgeon, the Mayo Clinic, Rochester, Minn.

JOHN ALEXANDER, M.A., M.D., Sc.D. (Hon., U of Pa.), F.A.C.S.

[Postoperative Atelectasis, Pulmonary Abscess, Gangrene and Bronchiectasis]

Professor of Surgery, University of Michigan, Surgeon in Charge, Section of Thoracic Surgery, University of Michigan Hospital, Ann Arbor, Mich., Chief Surgeon, Michigan State Sanatorium, Howell, Mich., Consulting Thoracic Surgeon to various hospitals and sanatoria

ARTHUR WILBURN ALLEN, A.B., M.D., F.A.C.S.

[Fractures of the Patella and Other Sesamoids]

Lecturer in Surgery, Harvard Medical School, Chief of East Surgical Service, Massachusetts General Hospital, Boston

EDWARD ALLEN, S.B., M.D., F.A.C.S.

[Disturbances of Menstruation]

Associate Clinical Professor of Obstetrics and Gynecology (Rush), University of Illinois, Associate Obstetrician and Gynecologist, Presbyterian Hospital, Chicago

WILLIAM DEWITT ANDRUS, M.D.

[Tumors of the Sympathetic Nervous System, Tumors and Cysts of the Mediastinum]

Associate Professor of Surgery, Cornell University Medical College, Attending Surgeon, New York Hospital, New York City

CHARLES BAGLEY, Jr., A.B., M.D., F.A.C.S.

[Brain Abscess]

Professor of Neurological Surgery, University of Maryland Medical School

ORVILLE TAYLOR BAILEY, A.B., M.D.

[Gastric Ulcer]

Associate in Pathology, Harvard Medical School, Boston

DONALD CHURCH RALFOUR, M.B., M.D., Hon.

LL.D. (Carleton Tor and St. Olaf), Hon.

D.Sc. (McMaster and Northwestern), **F.A.C.S.**

Hon. **F.R.C.S.** (Eng. and Aust.), Hon.

F.R.S.M. (Eng.)

[Tumors of the Stomach]

Professor of Surgery, Graduate School, University of Minnesota, Director the Mayo Foundation for Medical Education and Research, University of Minnesota, Head of Section in Division of Surgery, the Mayo Clinic, Rochester, Minn.

HOWARD C. RAILLINGER, M.D., F.A.C.S.

[Infections of the Nasal Accessory Sinuses]

Associate Professor of Otolaryngology, Northwestern University Medical School, Surgeon Department of Otolaryngology, Evanston Hospital, Evanston, Ill.

BENJAMIN STOCKWELL BARRINGER, B.S., M.D., F.A.C.S.

[Tumors of the Bladder]

Associate Professor of Surgery, Cornell University, Surgeon, Memorial Hospital, New York City

CLAUDE S. BECK, A.B., M.D., Sc.D., F.A.C.S.

[Surgery of the Heart and Pericardium]

Professor of Neurosurgery, Western Reserve University School of Medicine, Associate Surgeon, Lakeside Hospital, Cleveland, Colonel, U.S.A., Surgical Consultant, Fifth Service Command, Columbus, Ohio

J. DEWEY RISGARD, A.B., M.D., F.A.C.S.

[Unusual Hernias]

Associate Professor of Surgery, University of Nebraska College of Medicine, Visiting Staff Surgeon, University Bishop Clarkson Memorial, Nebraska, Methodist, Immanuel Lutheran, St. Joseph's Hospitals, Omaha, Nebraska

WILLIAM PAPIN BLAIR, M.D., F.A.C.S.

[Repair of Defects of the Face, Hands and Feet]

Professor Emeritus of Clinical Surgery, Washington University School of Medicine, Professor Emeritus of Oral Surgery, Washington University School of Dentistry, Associate Surgeon, Barnes St. Louis Children's, and St. Louis Maternity Hospitals, St. Louis

ALFRED BLALOCK, M.D.

[Abnormalities of the Thymus, Traumatic Shock]

Professor of Surgery, Johns Hopkins University School of Medicine, Surgeon in Chief, Johns Hopkins Hospital, Baltimore

**WILLIAM ROYD M.D., LL.D., M.R.C.P. (Edin.),
F.R.C.P. (Lond)**

[Inflammation]

Professor of Pathology and Bacteriology Uni-
versity of Toronto Pathologist Toronto General
Hospital Toronto

THEODORE PRFWITT BROOKES M.D. F.A.C.S.
[Dislocation of the Spine]

Assistant Professor of Clinical Orthopedic Sur-
gery Washington University School of Medicine
Assistant Surgeon Barnes and St. Louis Children's
Hospitals Orthopedic Surgeon Lutheran Dea-
coness and the City Hospitals St. Louis

JAMES BABBITT BROWN M.D. F.A.C.S.

[Repair of Defects of the Face Hands and Feet]
Associate Professor of Clinical Surgery Washing-
ton University School of Medicine Consulting
Surgeon Shriners Hospital Visiting Surgeon City
Hospital Surgeon Barnes and St. Louis
Children's Hospitals St. Louis Colonel MC.
AUS

ALFONDER BRUNSCHWIG M.S., M.D. F.A.C.S.
[Tumors of the Breast]

Professor of Surgery University of Chicago

STERLING DUNFELI D.S., M.D.

[Injuries of Tendons]

Civilian Consultant U.S.A. San Francisco

**CYRUS EDGAR BURHORD Ph.R. M.D. LL.D.,
F.A.C.S.**

[Chronic Prostatitis and Seminal Venenitis]

Professor and Director of Urology St. Louis Uni-
versity School of Medicine Urologist St. Mary's
Firmat Desloge St. Luke's Missouri Baptist,
Jewish and Bethesda Hospitals St. Louis

LOUIS T. RYARS M.D. F.A.C.S.

[Repair of Defects of the Face Hands and Feet]

Assistant Professor of Clinical Surgery Washing-
ton University School of Medicine St. Louis

***JAMES A. CAMMIE JR. M.D. F.A.C.S.**

*[Anomalies Injuries and Foreign Bodies of the
Colon Diverticulitis Fistula and Ulcerative
Colitis]*

Professor of Surgery and Director of the Depart-
ment of Surgery Georgetown University School of
Medicine Chief Surgeon Georgetown University
and Providence Hospitals Consulting Surgeon,
Columbia and Gallinger Municipal Hospitals
Washington D.C. Consulting Surgeon Tubercu-
losis Hospital Glendale Md.

***WILLIS C. CAMPBELL M.D. F.A.C.S.**

*[General Considerations of Dislocations Dislocation
of the Shoulder]*

Late Professor of Orthopedic Surgery University
of Tennessee College of Medicine Chief of Staff
Dr. Willis C. Campbell Clinic, Crippled Children's

* Deceased.

Hospital Hospital for Crippled Adults; Consulting
Orthopedic Surgeon Baptist Memorial St. Joseph's
and U.S. Marine Hospitals Attending Orthopedic
Surgeon Methodist Hospital Memphis Tenn.

**JAMES THOMAS CASE M.D., D.M.R.F. (Camb.)
F.A.C.S.**

*[Diagnostic and Therapeutic Roentgenology in
Surgery]*

Professor of Radiology Northwestern University
Medical School Radiologist Passavant Memorial
and U.S. Marine Hospitals Chicago and High-
land Park (Illinois) Hospital

RICHARD B. CATTELL M.D.

*[Anomalies Injuries and Foreign Bodies of the
Colon Diverticulitis Fistula and Ulcerative
Colitis]*

Surgeon Lahey Clinic New England Desconess
Hospital New England Baptist Hospital Boston,
Mass.

HENRY W. CASE AR M.D., F.A.C.S.

[Umbilical and Ventral Hernia]

Clinical Professor of Surgery College of Physi-
cians and Surgeons Columbia University Attend-
ing Surgeon Roosevelt Hospital New York City

FREMONT A. CHANDLER M.D. F.A.C.S.

[Tuberculosis of the Bones and Joints]

Professor and Director of Department of Ortho-
pedic Surgery University of Illinois Medical
School Senior Attending Orthopedic Surgeon St.
Luke's Hospital Chicago

FREDERICK CHRISTOPHER B.S. M.D., F.A.C.S.

*[Rabies Erysipelas Ganglion Developmental An-
omalies of the Cervical Region]*

Associate Professor of Surgery Northwestern Uni-
versity Medical School Chief Surgeon Evanston
Hospital Evanston Ill.

EDWARD DELOS CHURCHILL B.S., M.A. M.D.

*[The Scope and Nature of Military Surgery Tumors
of the Lung and Bronchi]*

John Homans Professor of Surgery, Harvard Uni-
versity Chief of the West Surgical Service Massa-
chusetts General Hospital Boston Colonel MC.
AUS

LOUIS H. CLEFF M.D., LL.D., F.A.C.S.

[Larynx and Trachea]

Professor of Laryngology and Bronchology Jefferson
Medical College Attending Bronchologist Jeffer-
son Hospital Laryngologist to the Radiologic
Clinic Philadelphia General Hospital Consulting
Bronchologist Rush Philadelphia General Ger-
mantown and St. Mary's Hospitals

GEORGE MOBBISON COATES A.B., M.D.

[Surgery of the Ear]

Professor of Otorhinology Graduate School of
Medicine University of Pennsylvania Emeritus
Professor of Otolaryngology, School of Medicine,

CONTRIBUTORS

University of Pennsylvania, Otorhinologist to Graduate Hospital Philadelphia Director of Department of Otolaryngology, Abington (Pa.) Memorial Hospital Consulting Otolaryngologist, University, Presbyterian and Germantown Hospitals Philadelphia and Chester County Hospital, West Chester, Pa

WARREN H COLE M.D., F.A.C.S.

[Tumors of the Gallbladder and Bile Ducts]

Professor of Surgery, University of Illinois College of Medicine, Chicago

BRADLEY LANCASTER COLEY, B.A., M.D., F.A.C.S.

[Femoral Hernia]

Visiting Surgeon Lincoln Hospital Attending Surgeon Memorial Hospital and Hospital for Special Surgery (formerly Hospital for Ruptured and Crippled) New York City, Assistant Professor of Clinical Surgery Cornell University Medical College, Surgeon in Chief, Mary McClellan Hospital, Cambridge N.Y., Colonel, M.C., A.U.S.

FREDRICK AMASA COLLER, B.S., M.S., M.D., F.A.C.S.

[Acidosis and Alkalosis Water and Electrolyte Balance]

Professor of Surgery and Chairman of Department of Surgery University of Michigan Ann Arbor, Mich

RAIPHI COLP, A.B., M.D., F.A.C.S.

[Postoperative Care]

Clinical Professor of Surgery Columbia University; Attending Surgeon Mount Sinai Hospital Consulting Surgeon Beekman, Beth Israel, Harlem Hospitals New York City

WILLIAM CONE R.Sc., M.D.

[Spina Bifida and Cranium Bifidum]

Associate Professor of Neurosurgery and Lecturer in Neuropathology Faculty of Medicine McGill University, Associate Professor, Department of Neurology and Neurosurgery Faculty of Graduate Studies and Research McGill University, Neurosurgeon Montreal Neurological Institute Montreal

H. FARLF CONWELL, M.D. F.A.C.S.

[Fractures of Ribs Clavicle and Scapula]

Consulting Orthopedic Surgeon Tennessee Coal, Iron and Railroad Company, and American Cast Iron Pipe Company, Birmingham Attending Orthopedic Surgeon St Vincent's South Highlands Children's and Hillman Hospitals Associate Surgical Director, Crippled Children's Clinic, Birmingham Ala

OLIVER COPE A.B., M.D.

[Thermal Burns]

Assistant Professor of Surgery Harvard Medical School Associate Visiting Surgeon, Massachusetts General Hospital, Boston.

JOHN S COULTER, M.D., D.T.M., F.A.C.S.

[Physical Medicine in Fractures]

Professor and Chairman Department of Physical Medicine Northwestern University Medical School Consultant Physical Therapy Department, St Luke's Illinois Central Passavant Memorial and Mexican Brothers Hospitals Chicago

VIRGIL S COUNSELLER, B.S., M.S., M.D.

[Iguanal Fistula]

Associate Professor of Surgery Mayo Foundation University of Minnesota

WINCHELL McK CRAIG R.A., M.D., M.S. (in Surgery) Sc.D. (Hon.) F.A.C.S.

[Tumors of the Peripheral Nerves]

Professor of Neurosurgery University of Minnesota Graduate School of Medicine Neurologic Surgeon the Mayo Clinic and St Mary's and Colonial Hospitals Rochester Minn Captain M.C., U.S.N., Chief of Surgery United States Naval Hospital National Naval Medical Center Bethesda Maryland

BROSON CROTHERS A.B., M.D.

[Birth Pains]

Clinical Professor of Pediatrics Harvard Medical School Visiting Physician Children's Hospital and Infants Hospital Boston

WILLIAM R CUBBINS B.Sc., M.D., F.A.C.S.

[Fractures of the Pelvis]

Professor of Surgery in Charge of Bones and Joints Loyola University; Surgeon St Luke's Hospital Attending Surgeon in Charge of a Fracture Ward Cook County Hospital Chicago

HARRY CULVER M.Sc., M.D. F.A.C.S.

[The Male External Genitals]

Associate Professor of Genito Urinary Diseases Northwestern University Medical School Urologist St Luke's and Cook County Hospitals, Chicago

GEORGE M CURTIS A.B., M.A., Ph.D., M.D., F.A.C.S.

[Diseases of the Lymphatic System]

Professor of Surgery and Chairman of Department of Surgical Research Ohio State University School of Medicine, Attending Surgeon Ohio State University Hospital Columbus Chief Surgeon, Franklin County Tuberculosis Hospital Columbus Licking County Sanatorium Newark Ohio

ELLIOTT CARR CUTLER M.D., D.Sc. Dr. (Hon. caus.), F.R.C.S. (Eng., Hon.)

[Gastric Ulcer]

Mosley Professor of Surgery Harvard Medical School Surgeon-in-Chief, Peter Bent Brigham Hospital Boston Brigadier General M.C., A.U.S., Chief Consultant in Surgery European Theater of Operations Chief of Professional Services Division European Theater of Operations

R A CUTTING M.D., C.M., M.A., Ph.D

[Postoperative Complications]

Professor of Physiology and Director of Department of Physiology Georgetown University School of Medicine Washington D C

WILLIAM CLARK DANFORTH B.S., M.D., F.A.C.S

[Tumors of the Uterus Endometriosus]

Professor of Obstetrics and Gynecology Northwestern University Medical School Chief of Division of Obstetrics and Gynecology, Evanston Hospital Evanston Ill

VERNON C DAVID A.R., M.D., F.A.C.S

[Benign Polypoid Tumors of the Large Bowel]

Rush Professor of Surgery University of Illinois Chairman of Surgical Department Presbyterian Hospital Attending Surgeon Cook County Hospital Chicago

DAVID M DAVIS B.S. M.D.

[Tumors and Cysts of the Kidney and Ureter]

Professor of Urology Jefferson Medical College; Attending Urologist, Jefferson Medical College Hospital Philadelphia

LOYAL DAVIS M.D. M.S., Ph.D. (in Surgery), D.Sc. (Hon.) F.A.C.S

[Trigeminal Neuralgia]

Professor of Surgery Chairman of Division of Surgery Northwestern University Medical School Attending Surgeon Passavant Memorial and Wesley Memorial Hospitals Chicago Consultant in Neurosurgery European Theater Colonel M.C., A.U.S.

MICHAEL DEBAKEY B.S., M.D., M.S. (Surgery)

[The Liver]

Assistant Professor of Surgery School of Medicine Tulane University of Louisiana Visiting Surgeon Charity Hospital Member of Adjunct Staff Touro Infirmary Member of Visiting Staff Mercy Hospital Associate in Surgery The Ochsner Clinic, New Orleans Lt. Col., M.C., A.U.S.

GÉZA DE TAKÁTS M.D., M.S., F.A.C.S

[Varicose Veins Venous Thrombosis Embolism]

Associate Professor of Surgery University of Illinois College of Medicine Senior Attending Surgeon St. Luke's and Research and Educational Hospitals Chicago Consultant in Vascular Surgery Veterans Administration Hines Illinois

EDWARD J DONOVAN B.S. M.D. F.A.C.S

[Congenital Malformations of the Stomach]

Associate Professor of Surgery College of Physicians and Surgeons Columbia University Attending Surgeon Babies Hospital Attending Surgeon, St. Luke's Hospital New York City

LESTER R DRAGSTEDT M.D., Ph.D

[The Parathyroid Glands The Adrenal Glands]

Professor of Surgery University of Chicago At

tending Surgeon Albert Merritt Billings Hospital Formerly Professor of Physiology and Pharmacology at Northwestern University Medical School Chicago

CARL EGGERS M.D., F.A.C.S

[The Esophagus]

Clinical Professor of Surgery New York University Attending Surgeon Lenox Hill Hospital Consulting Surgeon New York Post Graduate Hospital St. Vincent's Hospital New York City, and Lawrence Hospital Bronxville N Y

ELDRIDGE LYON ELIASON B.A., M.D., Sc.D., F.A.C.S

[Fractures about the Elbow Joint Dislocation at the Elbow]

Professor of Surgery University of Pennsylvania School of Medicine and University of Pennsylvania Graduate School of Medicine Surgeon University of Pennsylvania Philadelphia a General and Presbyterian Hospitals Philadelphia

LEO ELOESSER B.S., M.D., F.A.C.S

[Surgery of the Pleura]

Clinical Professor of Surgery Medical School of Stanford University Visiting Surgeon in Chief Stanford Service San Francisco Hospital Consulting Surgeon Veterans Administration and U S Public Health Marine Hospital Service San Francisco

SEWARD FRIEDMAN A.R. M.D., F.A.S.A., F.A.C.S

[General Considerations of Hernia Inguinal Hernia]

Assistant Professor of Clinical Surgery Cornell Medical College Attending Surgeon New York Hospital Consulting Surgeon New York Infirmary for Women and Children New York Eye and Ear Infirmary Morristown N J Memorial Hospital and Horton Memorial Hospital Middletown N Y

WILLIAM L ESTES Jr., A.B., M.D., F.A.C.S

[Fractures of the Tibia and Fibula Involving the Ankle]

Chief Surgeon St. Luke's Hospital Bethlehem Pa

WALTER A FANSLER A.M., M.D.

[Cryptitis Papillitis and Fissure in Ano]

Consulting Proctologist Glen Lake Sanatorium for Tuberculosis Proctologist Abbott Northwestern and St. Mary's Hospitals Minneapolis Clinical Professor of Surgery, University of Minnesota Associate Surgeon (in Charge of Proctology) Minneapolis General Hospital

JAMES IRVING FARRFELL B.S., M.S., Ph.D., M.D

[The Anatomy and Physiology of the Genitourinary Tract]

Associate in Urology and Research Instructor of Physiology Northwestern University Medical School Chief of Urologist Evanston Hospital Evanston Ill Lt. Com., M.C., U.S.N.R.

JOHN M. T. FINNEY, Jr., B.S., M.D., F.A.C.S.

[*General Principles of Preoperative Treatment*]

Associate in Surgery, Johns Hopkins Medical School, Baltimore, Lt Col, M.C., A.U.S.

WARFIELD M. FIROR, M.D.

[*Appendicitis*]

Associate Professor of Surgery, Johns Hopkins Medical School, Visiting Surgeon, Johns Hopkins Hospital, Baltimore

MORRIS T. FRIEDEL, B.S., M.D., M.S. (in Surgery)

[*Structure of the Bile Ducts*]

Formerly Assistant Surgeon, the Mayo Clinic, Rochester, Minn.; at present in Surgical Service, U. S. Naval Hospital, Philadelphia

IDIS M. GAGE, M.D., F.A.C.S.

[*Pilonidal Sinuses and Cysts*]

Associate Professor of Surgery, School of Medicine, Tulane University of Louisiana Assistant Chief of the Tulane Surgical Service, Charity Hospital, New Orleans, Senior Surgeon, Charity Hospital, New Orleans; Visiting Surgeon, Touro Infirmary, New Orleans, Consulting Surgeon Illinois Central Hospital, New Orleans, Colonel, M.C., A.U.S., Consulting Surgeon, Headquarters Fourth Service Command, Atlanta; Chief, Professional Service Branch Headquarters Fourth Service Command Atlanta, Organizer and Director, 24th General Hospital A.U.S., Tulane University Affiliated Unit

THOMAS CYRUS GALLOWAY, S.M., M.D.

[*Neoplasms of the Larynx*]

Associate Professor of Otolaryngology, Northwestern University Medical School and Cook County Post-Graduate Medical School, Attending Otolaryngologist, Cook County Hospital Chicago; Chief of Division of Otolaryngology, Evanston Hospital, Evanston, Ill.

WILLIS D. GATCH, B.A., M.D., F.A.C.S.

[*Infections and Tumors of the Small Intestine*]

Professor of Surgery and Dean, Indiana University School of Medicine, Attending Surgeon, St. Vincent's, Methodist, University and Indianapolis City Hospitals Indianapolis

CHARLES F. GESCHICKTER, M.D., Baltimore Md.

[*Tumors of Bone*]

Pathologist, U.S. Naval Medical School, Bethesda, Md.

RALPH KALB GHORMLEY, B.S., M.D., F.A.C.S.

[*Acute Suppurative Arthritis*]

Professor of Orthopedic Surgery, the Mayo Foundation University of Minnesota, Associate in Orthopedic Surgery, the Mayo Clinic, Rochester, Minn.

*SANFORD R. GIFFORD, M.A., M.D., F.A.C.S.

[*Injuries and Surgical Infections of the Eyes and Adnexa*]

Late Professor of Ophthalmology, Northwestern University Medical School, Attending Ophthalmologist, Passavant Memorial, Cook County, and Wesley Hospitals, Chicago

EDGAR LORRINGTON GILCREEST, A.B., M.D., F.A.C.S.

[*Surgery of the Muscles and Ligaments*]
San Francisco

ALBERT E. GOLDSTEIN, M.D., F.A.C.S.

[*Congenital Anomalies of the Genitourinary Tract*]

Associate in Genito-Urinary Pathology, University of Maryland, Chief of Genito-Urinary Department, Sinai Hospital Baltimore, Genito-Urinary Consultant, Mt. Pleasant Sanatorium for Tuberculosis, Reisterstown, Md. Medical Director Hebrew Home for Aged and Infirm Baltimore Director of Hoesberger Urological Research Laboratory, Sinai Hospital

A. STEPHENS GRAHAM, M.D., M.S. (in Surgery), F.A.C.S.

[*Carcinoma of the Colon Carcinoma of the Rectum and Anal Canal*]

Associate Professor of Surgery, Medical College of Virginia, Attending Surgeon, Stuart Circle and Medical College of Virginia Hospitals and Retreat for the Sick, Richmond Va. Surgical Consultant to the India, Burma and China Theaters, Lt Col, M.C., A.U.S.

EVARTS A. GRAHAM, A.B., M.D., F.A.C.S.

[*The Islands of Langerhans*]

Professor of Surgery Washington University, St. Louis, Surgeon in Chief Barnes and St. Louis Children's Hospitals St. Louis

FRANCIS CLARK GRANT, A.B., M.D.

[*Injuries of the Spinal Cord Treatment of Meningitis*]

Professor of Neurological Surgery Medical School University of Pennsylvania, Philadelphia

HOWARD K. GRAY, B.S., M.D., M.S. (in Surgery)

[*Cholecystitis Cholelithiasis, Choledocholithiasis, and Associated Diseases of the Liver*]

Head of Section in General Surgery Mayo Clinic; Mayo Clinic Associate Professor of Surgery Mayo Foundation Captain M.C. USNR

SAMUEL F. HAINES, B.S., M.D., M.S. (in Medicine)

[*Diseases of the Thyroid Gland and Their Management*]

Associate Professor, the Mayo Foundation of the University of Minnesota Head of Section in Medicine, the Mayo Clinic, Rochester Minn.

*Deceased.

JOHN MANN HANFORD A.B., M.D., F.A.C.S.*[Wounds of the Neck]*Associate Professor of Clinical Surgery College of Physicians and Surgeons Columbia University
Associate Attending Surgeon Presbyterian Hospital New York City**EDWARD M. HARRAHAN A.B., M.D. F.A.C.S.***[The Scalp]*

Associate in Surgery Johns Hopkins Medical School Assistant Visiting Surgeon in Plastic Surgery Johns Hopkins Hospital Visiting Plastic Surgeon Union Memorial Hospital and Women's Hospital Consultant in Plastic Surgery Baltimore City Hospital Baltimore

MAXWELL HARBIN B.S. M.D. F.A.C.S.*[Osteochondroma of the Growth Centers]*

Associate Clinical Professor of Orthopedic Surgery Western Reserve University School of Medicine Associate Orthopedic Surgeon Lakeside Hospital Cleveland Orthopedic Surgeon in Charge Rainbow Hospital for Crippled and Convalescent Children South Euclid Ohio

STUART W. HARRINGTON M.D. M.S. (in Surgery) F.A.C.S.*[Diaphragmatic Hernia]*

Head of Section on Thoracic Surgery and Professor of Surgery the Mayo Foundation Graduate School University of Minnesota Rochester Minn

(JULIAN) DERYL HART A.B., A.M., M.D. F.A.C.S.*[Injuries Due to Cold Injuries Due to Chemicals]*

Professor of Surgery Duke University School of Medicine Head of Surgical Department Duke Hospital Durham N. C.

HAROLD D. HARVEY M.D.*[The Peritoneum]*

Assistant Attending Surgeon Presbyterian Hospital New York City Associate in Surgery College of Physicians and Surgeons Columbia University

SAMUEL CLARK HARVEY M.D. Sc.D. (Hon.) F.A.C.S.*[Injuries and Infections of the Breast]*

William H. Carmalt Professor of Surgery Yale University School of Medicine Surgeon in Chief New Haven (Conn.) Hospital and New Haven Dispensary

JEROME R. HEAD A.M., M.D.*[Anatomy Physiology and Congenital Anomalies of the Thoracic Wall Pleura and Lungs Mediastinal Emphysema]*

Assistant Professor of Surgery Northwestern University Medical School Associate Surgeon Evanston (Ill.) Hospital Medical Director Edward Sanatorium Naperville Ill., Attending Surgeon Cook County Hospital Chicago

CASPER FRANK HEGNER M.D., F.A.C.S.*[Surgery of Pulmonary Tuberculosis]*

Formerly Professor of Surgery University of Colorado School of Medicine Consulting Surgeon Denver Episcopal Hospital for Children and Bethesda Sanatorium Denver, Colo., Formerly Chief Surgical Staff Colorado General Hospital Staff Member St. Joseph's St. Luke's and Mercy Hospitals Swedish National Sanatorium and Jewish Consumptive Relief Society Denver

MELVIN STARAFY HENDERSON M.B., M.D., F.A.C.S.*[Mechanical Derangements of the Knee Joint]*

Professor of Orthopedic Surgery the Mayo Foundation University of Minnesota Attending Orthopedic Surgeon the Mayo Clinic Attending Orthopedic Surgeon Colonial and St. Mary's Hospitals Rochester Minn

LOUIS G. HERRMANN A.B., M.D.*[Indolent Ulcers]*

Associate Professor of Surgery College of Medicine University of Cincinnati Assistant Director of the Surgical Services, Cincinnati General Hospital Director Vascular Disease Services Cincinnati General Hospital and the Christian R. Holmes Hospital University of Cincinnati Associate Surgeon Children's Hospital Cincinnati Ohio

Professor of Surgery College of Medicine University of Tennessee Senior Attending Surgeon Baptist Memorial Hospital Consulting Surgeon John Gaston Hospital Memphis, Tenn

EMILF HOLMAN B.A. (Oxon.) M.D. F.A.C.S.*[Congenital Abnormalities of the Vascular System Wounds Occlusive Diseases of the Peripheral Vessels Arteriosclerosis Syphilitic Endarteritis Erythromelalgia Amputations in Peripheral Vascular Disease Aneurysms]*

Professor of Surgery Stanford University Medical School Chief Surgeon Lane and Stanford Universities Hospitals San Francisco

CHARLES HUGGINS M.D.

[*Diverticula of the Urinary Bladder*]

Professor of Surgery (Urology) The University of Chicago Attending Urologist, Billings Memorial Hospital Chicago, Ill

ROBERT HENRY IVY, M.D., D.D.S., F.A.C.S.

[*Fractures of Facial Bones The Salivary Glands and Ducts The Jaws Dislocation of the Temporomandibular Joint*]

Professor of Plastic Surgery University of Pennsylvania, Chief of Plastic Surgery Graduate and University Hospitals Visiting Plastic Surgeon Presbyterian Hospital Consulting Plastic Surgeon Children's and Chestnut Hill Hospitals Philadelphia Colonel Medical Reserve Corps U.S. Army Civilian Consultant in Plastic Surgery Office of the Surgeon General U.S.A.

ARNOLD STEVENS JACKSON, B.A., B.S., M.D., M.S. (in Surgery) F.A.C.S.

[*Spinal Anesthesia*]

Attending Surgeon Methodist Hospital Madison Wis

W. KENNETH JENNINGS, B.S., M.S., M.D., F.A.C.S.

[*Minor Surgical Procedures*]

Attending Surgeon Cottage and St. Francis Hospitals Santa Barbara, Calif

JULIAN JOHNSON, A.B., M.D., D.Sc. (Med.)

[*Fractures about the Elbow Joint Dislocation at the Elbow*]

Associate in Surgery University of Pennsylvania Medical School Assistant Surgeon University of Pennsylvania Hospital Philadelphia Major M.C., U.S.A.

ROBERT W. JOHNSON, Jr., A.B., M.D.

[*Congenital Deformities—Part I*]

Associate in Orthopedic Surgery Johns Hopkins Medical School Visiting Orthopedic Surgeon Johns Hopkins Hospital Assistant Director Children's Hospital Baltimore

*EDWARD STARR JUDD, M.D., F.A.C.S., D.Sc.

[*Cholecystitis Cholelithiasis Choledocholithiasis and Associated Diseases of the Liver*]

Late Chief of the Surgical Staff the Mayo Clinic and Professor of Surgery the Mayo Foundation, Graduate School of the University of Minnesota

ROBERT H. KENNEDY, B.A., M.D., F.A.C.S.

[*General Discussion of Fractures Compound Fractures*]

Associate Clinical Professor of Surgery Columbia University Surgical Director Beekman Hospital Attending Surgeon New York Post-Graduate Hospital New York City Colonel M.C., A.U.S.

* Deceased

JIMMIE ALBERT KEY, B.S., M.D.

[*Some Diseases of Bone That Are Not Infectious in Origin*]

Clinical Professor of Orthopedic Surgery, Washington University School of Medicine Associate Surgeon Barnes Children's and Jewish Hospitals St. Louis

NORMAN T. KIBIK, M.D.

[*Prosthesis*]

Major General Surgeon General U.S.A.

RALPH T. KNIGHT, B.A., M.D., F.A.C.S.

[*General Anesthesia*]

Clinical Professor of Anesthesiology University of Minnesota Graduate School of Medicine and Medical School Director of Division of Anesthesiology Director of Anesthesia University of Minnesota Hospitals Minneapolis General Northwestern Asbury St. Barnabas St. Mary's Norwegian Lutheran Deaconess Minneapolis and Charles T. Miller Hospitals St. Paul Consultant in Anesthesiology U.S. Veterans Administration Hospital Minneapolis

SUMNER L. KOCH, M.A., M.D., F.A.C.S.

[*Infections of the Tendon Sheaths of the Hand and of the Facial Spaces of the Palm*]

Associate Professor of Surgery Northwestern University Medical School Attending Surgeon Pasavant Memorial and Cook County Hospitals Chicago

HEBMAN L. KRETSCHEMER, M.D., F.A.C.S., D.Sc. (Bio.)

[*Other Affections of the Prostate*]

Clinical Professor of Surgery (Urology) Rush Medical College University of Illinois Head of Dept. of Urology Presbyterian Hospital Consulting Urologist Children's Memorial Hospital Chicago President American Medical Association

WILLIAM EDWARDS LADD, A.B., M.D., F.A.C.S.

[*Anomalies of the Small Intestine Congenital Obstruction of the Bile Ducts*]

William F. Ladd Professor of Child Surgery Harvard Medical School Chief of Surgical Service Children's Hospital Boston

MAURICE LEFZ, M.D.

[*Radiotherapy in Cancer of the Breast*]

Chief of Radiotherapy Department Presbyterian Hospital Professor of Clinical Radiology College of Physicians and Surgeons Columbia University Consulting Radiotherapist Montefiore and the Manhattan Eye, Ear, Nose and Throat Hospitals New York City

PHILIP LEWIS, B.S., M.D., F.A.C.S.

[*Common Disturbances of the Foot and Ankle*]

Associate Professor of Bone and Joint Surgery Northwestern University Medical School Professor of Orthopedic Surgery Cook County Graduate

School of Medicine Attending Orthopedic Surgeon Cook County and Michael Reese Hospitals, Chicago Lt Col., M.C., A.U.S. Chief of Orthopedic Surgery Section Mayo General Hospital Galesburg Ill

MANUEL EMIL LICHTENSTEIN B.S. M.S. M.D., F.A.C.S.

[*Fractures of the Metacarpals and Phalanges*]

Assistant Professor of Surgery Northwestern University Medical School Attending Surgeon Norwegian American Hospital Associate Surgeon Cook County Hospital, Chicago Lt Col. M.C., A.U.S.

JENNINGS CRAWFORD LITZBERG B.S., M.D., F.A.C.S.

[*Ectopic Pregnancy*]

Professor of Obstetrics and Gynecology Eminent Medical School University of Minnesota

PREFACE TO THE FOURTH EDITION

The greatly increased utilization of the third edition of this textbook not only in military but also in civilian practice has imposed upon the editor and the contributors a distinct obligation to bring the fourth edition completely up to date and make it a cross sectional presentation of the best in American Surgery.

Of special value in this edition are two entirely new sections one on Military Surgery by Colonel Edward D. Churchill Consultant in Surgery in the North African Theater and Professor of Surgery at Harvard Medical School and the other on Chemotherapy in Surgical Infections by Dr. John S. Lockwood Associate Professor of Surgery, Yale Medical School. The latter explains fully the uses of penicillin and the sulfonamides. Other entirely new sections include the following: *Actinomyces* by Dr. Owen H. Wangenstein Professor of Surgery, University of Minnesota Medical School; Burns by Dr. Oliver Cope Assistant Professor of Surgery, Harvard Medical School; Shock by Dr. Alfred Blalock Professor of Surgery, Johns Hopkins Medical School; Indolent Ulcers by Dr. Louis G. Herrmann Associate Professor of Surgery, University of Cincinnati Medical School; Vascular Tissue Tumors by Dr. Arthur Purdy Stout Professor of Surgical Pathology, *Columbus University*; Tumors of the Sympathetic Nervous System by Dr. William DeW. Andrus Associate Professor of Surgery, Cornell University Medical School; Fractures of the Radius and Ulna by Dr. Harrison L. McLaughlin Associate Professor of Surgery, Columbia University; Tumors of the Breast by Dr. Alexander Brunschwig Professor of Surgery, University of Chicago; Inflammations of the Chest Wall by Dr. William E. Adams Associate Professor of Surgery, University of Chicago; Wounds of the Thorax by Dr. William F.

Rienhoff Jr. Associate Professor of Surgery, Johns Hopkins Medical School; Pilonidal Sinuses and Cysts by Colonel Idys Mims Grice Associate Professor of Surgery, Tulane University; The Peritoneum by Dr. Harold D. Harvey Associate Professor of Surgery, Columbia University; Diverticulitis and Ulcerative Colitis by Dr. Richard B. Cattell of the Lahey Clinic; Unusual Hernias by Dr. J. Dewey Bigsard Associate Professor of Surgery, University of Nebraska Medical School; Diverticuli of the Urinary Bladder by Dr. Charles Huggins Associate Professor of Surgery, University of Chicago; Diseases of the Vulva by Dr. H. Close Hesselbom Associate Professor of Gynecology, University of Chicago; and Vaginal Fistula by Dr. Virgil S. Counseller of the Mayo Clinic.

Two contributors have been lost by death, Dr. Mont R. Reid whose section on Wounds has been revised by Dr. Jonathan E. Rhoads Professor of Surgery, University of Pennsylvania, and Dr. Sanford R. Gifford. The sections on dislocations written by the late Willis C. Campbell have been revised by Dr. J. Spencer Speed Professor of Orthopedic Surgery, University of Tennessee, and Dr. Everts A. Graham's section on the Islands of Langerhans has been revised by Dr. Nathan A. Womack Professor of Surgery, Washington University Medical School. Especially extensive revisions have been made by Dr. Geza de Takats of the sections on Varicose Veins and Venous Thrombosis and by Dr. James C. White of the section on the Autonomic Nervous System.

The editor wishes to thank the contributors for their enthusiasm and loyal cooperation in helping to make this an up to date practical treatise on surgery.

FREDERICK CHRISTOPHER

EVANSTON HOSPITAL
EVANSTON, ILLINOIS

PREFACE TO THE FIRST EDITION

The dominant plan of this textbook is to give the student a concise presentation of surgery which is characterized by the maximum authority. The many advances in different branches of surgery which have been made in recent years have rendered it impossible for any one person to be experienced in and intimately acquainted with all of them. The plan of collaboration has been employed successfully in internal medicine and in the various surgical specialties.

The contributors whose painstaking work has made this book possible have been chosen after careful thought and consultation because of their outstanding ability in the subjects which they present. With few exceptions these men are actively engaged in teaching surgery to medical students. Each contributor has presented his material in the manner he has found to be most successful in instructing his students.

The subject matter contains the tested and accepted present day principles of surgery. Debatable or incompletely tried methods are not included. Where the author may show a personal preference to a particular line of treatment he has been careful to present other well known and acceptable methods. Etiology, pathology, and diagnosis have properly been stressed and the correct surgical treatment has been carefully described.

The editor can only inadequately express his gratitude to the many who have helped him in the preparation of this book. First of all is an appreciation of the fine spirit of loyalty and cooperation shown by the contributors. It is their book. Secondly, go thanks to many individuals who have helped. The wise and friendly counsel of Dr E. Starr Judd was of first importance

to the undertaking. By his lamentable death the nation lost an outstanding surgeon whose vast amount of work was characterized by calm, clear judgment and brilliant manual dexterity. Dr Loyal Davis has given valuable aid in the selection of the contributors to the section on Neurological Surgery. The advice of Dr Sumner L. Koch in formulating the underlying principles of presentation and teaching values is much appreciated. Drs Clay Ray, Murray, Jerome P. Webster and Roscoe C. Welsh have given enthusiastic and understanding assistance. Drs Dean D. Lewis, Frederic W. Bancroft, Vernon C. David, George J. Heuer and others have given valuable advice. Dr William C. Danforth has helped in the selection of the contributors to the gynecological section and has edited their manuscripts. Since receiving their excellent manuscripts the editor has learned with great regret of the deaths of Drs John F. Connors and W. V. Mullin.

My associates Dr W. Kenneth Jennings and Dr H. R. Reichman have helped greatly in the editorial work. Miss Dorothy Watt, of the editorial department of the American Medical Association has assisted in the preparation of the manuscripts and in the proofreading. Mr. Tom Jones has given invaluable help in the selection, arrangement and improvement of the illustrations. Miss Mary Dixon of the Art Department of Northwestern University Medical School has retouched and redrawn many of the figures.

The editor is greatly indebted to W. B. Saunders Company for encouragement and many constructive suggestions.

I. INFLAMMATION AND REPAIR OF TISSUE

INFLAMMATION

Inflammation is the most fundamental of all pathologic processes from the point of view of the surgeon. It is the local reaction of the body to irritation and not only is the surgeon concerned with removing irritants and aiding the tissues to resist their action but he produces some degree of inflammation with every stroke of the knife. Moreover inflammation blends so imperceptibly with the process of repair that it is impossible to say in any given case where one ceases and the other begins.

Causes—To enumerate the causes of inflammation would merely be to give a list of every known irritant. The chief surgical irritants are pathogenic micro organisms, physical and chemical agents and trauma. Animal parasites are of little importance in this respect. Physical irritants include for example, radiation (x rays and radium), electricity, heat and cold. Among the most important surgical chemical irritants are antiseptics. Trauma if severe enough will produce inflammation for reasons which will presently be explained.

The Nature of Inflammation—The object of the inflammatory process is to neutralize and remove an irritant. In the higher animals and in man this attempt is associated with striking changes in the blood vessels. These changes, although responsible for such clinical manifestations of inflammation as heat, redness, swelling and pain, are not the essence of the process. Metchnikoff long ago demonstrated that inflammation is the local reaction of the tissues to irritation, is present in animals which have no vascular system as well as in those supplied with blood vessels. The essential element in inflammation in all animals from the highest to the lowest is the reaction of the wandering mesodermal cells against an irritant. In the higher animals these cells are for the most part within blood vessels in the form of leukocytes, although the wandering cells of the tissues also play an important part. As the leukocytes are inside the vessels

while the irritant is outside it is obvious that by some device they must be transferred from the inside to the outside. Moreover the body fluids also play a part in the neutralization of bacterial toxins in the formation of fibrin and in other ways and as these fluids are for the most part inside the vessels they also must escape to the outside. The series of steps by which the contents of the blood vessels are transferred from the inside to the outside constitute the vascular phenomena and they are responsible for the clinical signs of inflammation.

The above description speaks of object and purpose. Such a teleological explanation is convenient and appeals to the practical surgeon, but strictly speaking it is not justifiable. The events of the inflammatory process are impersonal physicochemical phenomena which have developed in the course of evolution because those animals able to react to injurious irritants in this manner survived while those unable to do so perished.

The Vascular Phenomena—In order to bring about the results just outlined two factors are necessary: (1) an increased supply of blood must be brought to the part; (2) the permeability of the vessels must be greatly increased. The all important increase in vessel permeability must be due to some locally produced agent. Sir Thomas Lewis has shown that the flushing of the skin which follows firm stroking is due to the action of a histamine-like substance (II substance). Histamine increases vessel permeability in addition to producing dilatation. As Lewis puts it: "The agent which alarms the garrison and mobilizes the first or vascular defences is a chemical agent derived from the tissues. Menkin in an extended series of studies has succeeded in isolating from experimentally produced inflammatory exudates factors which appear to play an important part in the process. One of these factors he calls *leukotaxine* because it increases capillary permeability to a marked degree and thereby permits outward passage of leukocytes. It seems to be an intermediary breakdown product of pro-

tein metabolism. When this substance is injected locally the increased capillary permeability is followed by rapid migration of polymorphonuclear leucocytes. It is definitely chemotactic. Another factor in the exudate is capable of causing a marked increase in the number of circulating leucocytes in the normal animal.

The result of the alarm and mobilization of the garrison referred to by Lewis is the series of vascular changes first described by Colin Clark in 1877 which form a striking phenomenon when viewed in the living animal but which can also be studied at lei-

is certain to result in necrosis of some of the tissue involved.

With slowing of the blood stream there is a rearrangement of the blood cells. The leucocytes fall out of the central current and are dragged along the walls to which here and there they adhere until finally the vessel wall is lined by these cells a condition known as pavementing. This is brought about by an increased stickiness of the leucocytes due to an alteration in surface tension this change being in turn caused by bacterial or other toxins which have penetrated the wall of the vessel. The wall itself

Fig 1 — Acute inflammation showing vascular dilatation, swelling of endothelium, loosening of the texture of the wall and outwandering of leucocytes to form the inflammatory exudate. $\times 600$

sure in fixed tissues. The small vessels after a brief preliminary contraction undergo marked dilatation so that the part becomes flooded with blood and an enormous number of capillaries come into view which previously were invisible. This is the cause of the reddening which is so characteristic a feature of inflamed tissue and also of the increased heat of the part. Although temporarily quickened the blood flow soon becomes slowed and the leucocytes the total number of which may by this time be increased accumulate within the vessels. Should the irritation be severe there may be complete stoppage or stasis of the blood flow followed by thrombosis an event which

is meanwhile undergoing a change. The endothelial cells become greatly swollen and project into the lumen thus assisting in no small measure the tendency to slowing of the flow. In addition the wall of the vessel appears to become looser in texture so that the outlines of its constituent parts are lost and it becomes more or less of a protoplasmic sponge. It will readily be appreciated how these changes which are seen particularly in the venules and capillaries affect the permeability of the vessel wall so that the contents can pass from the lumen into the surrounding tissue and thus gain access to the irritant.

It is not necessary to describe in detail

the well known process of the emigration of the leukocytes (Fig 1) the motive power of which appears to be an alteration of surface tension on the side next to the vessel wall produced by some diffusible chemical agent such as Menkin's leukotaxine. The first of the blood cells to pass through are the polymorphonuclear leukocytes and these may be followed later by monocytes, lymphocytes and erythrocytes. The plasma also escapes through the permeable vessel wall. In the vicinity of the vessel these various elements together with additions from the tissues form the inflammatory exudate.

Inflammatory Exudate.—The inflammatory exudate which forms at the seat of irritation is partly cellular and partly fluid in character. The cells are derived from the blood and from the tissues; the fluid comes from the blood. It is evident that the composition of the exudate will vary enormously depending largely on the nature and intensity of the irritant. Consider for a moment the following irritants: *Staphylococcus aureus*, anthrax bacillus, *Treponema pallidum*, the sting of a bee, a surgical knife and a sprain. For each of these the type of exudate produced will be markedly different from that found in the others. In this brief review of the inflammatory process a detailed analysis of these variations is impossible but they must be kept in mind in interpreting what follows.

The polymorphonuclear leukocyte is the principal cell in the acute inflammatory reaction to a pyogenic bacterium and it constitutes the chief element of ordinary pus so that it is commonly spoken of as a pus cell. It is derived entirely from the blood. In acute inflammation the number of these cells in the blood is greatly increased and as they are formed in the bone marrow it is evident that some chemical agent (such as Menkin's leukotaxine producing factor present even in non bacterial inflammatory exudates) must be carried from the seat of the inflammation to the marrow by the blood stream. The appearance they present depends largely on their freshness. They are seen to best advantage in an acute gonorrheal discharge where they escape at once from the body. When retained within the tissues for some time they suffer at the hands of the bacterial toxins and either lose

their sharpness or are completely disintegrated. They are actively phagocytic for bacteria and form the first line of cellular defense. On disintegrating they liberate proteolytic ferments which liquefy the dead tissue and thus play an essential part in the production of pus.

The eosinophilic leukocyte plays no part of importance in an acute inflammatory process but in subacute and chronic inflammatory conditions it is sometimes present in large numbers. In subsiding appendicitis it may form one of the chief constituents of the exudate. Many of the cells may be derived from the tissues as well as from the blood.

The lymphocyte is the chief element of the familiar 'small round cell infiltration' which is the characteristic reaction to a mild or chronic irritant and is present in enormous numbers in tuberculosis and syphilis. In spite of this fact its function in inflammation is at present unknown. Most of these cells are derived from the tissues but it is possible that some may come from the blood.

The plasma cell is probably derived from the lymphocyte and it appears under similar conditions. It is particularly characteristic of syphilitic lesions and often forms the principal cell in chronic inflammation of joints.

The histiocyte or macrophage (the former name indicating its origin, the latter its appearance and function) is one of the most important elements of the inflammatory exudate on account of its great phagocytic power. It is seen in the later stages of inflammation where it plays the part of a scavenger cell for dead material but it also forms the principal cellular defense against many bacterial and protozoal infections. Most if not all of these cells are histogenous in origin being derived from the wandering elements of the reticuloendothelial system, the histiocytes of the tissues. They give rise to the epithelioid cells of tuberculosis and other chronic inflammations and when they fuse together they form the familiar foreign body giant cells.

Red blood cells form a prominent part of the exudate in hemorrhagic inflammations of which anthrax is an excellent example. Here there is actual destruction of the cap-

illary wall but it is probable that red cells can pass through a wall which is damaged but still intact

The *lymph of the exudate* is derived from the blood and represents an outflow so great that the lymphatics are unable to cope with it so that it accumulates in the tissues. The amount of lymph depends partly on the nature of the irritant and partly on the type of tissue (open or dense) in which the exudate occurs. In some forms of inflammation it forms the bulk of the exudate e. g. in the sting of an insect.

Fibrin is formed from the lymph of the exudate being the resultant of the action of the thrombin liberated by disintegration of the blood platelets on the fibrinogen of the plasma. The amount formed will again depend on the nature of the irritant and on the site of the exudate. Pneumococcal and diphtheritic exudates are usually rich in fibrin and it is on serous membranes that it is formed most abundantly. Fibrin forms the scaffold on which the superstructure of repair is erected. It is also responsible for the formation of adhesions which tend to limit the spread of the inflammatory process.

The Localization of Infection—The inflammatory reaction tends to prevent the dissemination of infection. Speaking generally, the more intense the reaction the more likely is the infection to remain localized. Much depends on the nature of the infecting agent. *Staphylococci* produce an acute inflammatory lesion in which the bacteria tend to remain confined to the lesion owing perhaps at least in part to the coagulase which they produce. *Streptococci* tend to spread through the tissues and along lymph channels aided in this by the fibrinolysin which they form.

Meakin has called attention in experimental inflammation to the importance of mechanical obstruction in limiting the spread of infection. This obstruction is due partly to the formation of a network of fibrin and partly to occlusion of the lymphatic channels. The mechanical factors tend to cause what may be called *fixation* of the infective agent in the early stages before phagocytes have time to accumulate.

Changes in the Tissues—An irritant affects not only the blood vessels and their contents but the tissues with which it comes

in contact. The tissue change depends on the nature and intensity of the irritant. Any irritant if weakened sufficiently becomes a stimulant and the further a tissue is from the site of the irritant the stronger will be the tendency to stimulation rather than destruction. The effect of stimulation is hyperplasia but as this is concerned with the subject of repair it will not be considered further here. Only the changes produced in the neighborhood of an acute irritant such as one of the pyogenic cocci will be discussed.

The bacterial toxins first cause cellular degeneration (cloudy swelling fatty degeneration) and then death (necrosis) of the tissue all the more readily if vascular stasis and thrombosis have occurred. The fate of the dead tissue depends in a large extent on the number of leucocytes present. When these are numerous they liberate during disintegration a proteolytic ferment sufficient in amount to cause liquefaction of the dead tissue. Thus at the site of the acute irritant liquefied necrotic material inflammatory lymph in which fibrin formation is inhibited by the action of the ferments and polymorphonuclear leucocytes are found. The resulting mixture is known as pus and the process of production is called suppuration. If the process is localized in abscess is formed if it is diffuse and spreading the result is cellulitis.

Pus is a yellowish material with an alkaline reaction containing leucocytes which may or may not be well preserved occasional lymphocytes mononuclears and necrotic tissue cells and living or dead bacteria. It does not coagulate because of the enzymes of the leucocytes thus the pus of empyema will not clot when removed from the body although the serous exudate of pleurisy will form a thick jelly under similar circumstances. Its physical characters depend on the infecting organism. *Staphylococcal* pus is creamy in consistency and has a mawkish odor streptococcal pus is sero-fibrinous and without odor. *Bacillus coli* pus has a characteristic fecal odor. *B. pyocyaneus* pus is greenish or blue tuberculous pus is flaky.

Chronic Inflammation—This is the reaction of the tissues to a low grade of irritation which may be bacterial or non bacte-

rial The principal cells are lymphocytes, plasma cells and macrophages all of which are probably histogenous in origin Polymorphonuclears are few or absent Fibroblastic proliferation followed later by fibrosis is always a marked feature In its purest form it is seen around a foreign body Two examples of special surgical interest are leopodium granuloma and traumatic fat necrosis *Lycopodium granuloma* is the result of a granulomatous reaction around the dead spores of the club moss *Lycopodium clavatum* which constitute the leopodium powder used for dusting surgical gloves The lesion consists of an area of necrosis lymphocytes epithelioid cells multinucleated giant cells and fibroblasts The large spores which are stained a bright red in Ziehl Nielsen preparations serve to distinguish the lesions from tubercles The small nodules which may be scattered over the peritoneum may be mistaken for a previous operation may be mistaken by the surgeon for tubercles Similar lesions are caused by the talc crystals of talcum powder *Traumatic fat necrosis* is the result of injury to the fat cells of the subcutaneous tissue of the breast A chronic inflammatory reaction develops around the necrotic tissue characterized by the presence of foreign body giant cells and later by fibrosis The resulting nodule may also be mistaken for an infective lesion

THE REPAIR OF TISSUE

Since the science of surgery is primarily dependent on the ability of tissue to repair itself knowledge of the processes of repair

and the extent to which restoration of normal structure may be expected is essential to the surgeon While highly specialized tissue such as the kidneys brain and glandular organs repair injuries to themselves by the formation of fibrous tissue other less specialized tissue may rebuild itself in a form almost identical with the normal structure John McCrae has expressed this difference in a striking comparison

The parenchymatous cell is the professional man in a community specially trained not to be replaced by one of his own class impressionable by even slight external stimuli, not prone to be physically hardly not overgiven to reproduction The supporting cell on the other hand is its laboring-class brother not trained in any high special task whose supportive work can be replaced by any kind of tissue even scar tissue not readily impressionable even by powerful external stimuli physically strong and ready in reproduction These two cells side by side in the kidney exposed to the same toxic influences but reacting to them each in its own way A toxin strong enough seriously to damage the high-class cell is only strong enough to irritate the low-class cell to reproduction When the high-class cell is killed by toxins there is absence of regeneration by the remaining tubular cells and it leaves no one of its kind in its stead Its place is occupied but its function is not performed by the progeny of its laboring class brother

PHYSIOLOGY OF REPAIR

The repair of tissue is stimulated by the injury to the tissue cells whether the injury is an intentional division as in an operation or accidental The damaged cells liberate a tissue extract which calls forth a fibroplastic response from the surrounding tissue The work done by Menkin¹ further confirms this theory He has for the sake of convenience named the active substance 'leukotoxine' It is capable of rapidly initiating the usual sequences of inflammation by inducing a prompt increase in capillary permeability and by causing an extremely rapid aggregation and migration of leukocytes through the endothelial wall The fibrin trabeculae in the exudate and blood clot form the framework for subsequent tissue growth In small incised wounds repair begins earlier than in large surface wounds so that factors other than the liberation of tissue juices are involved In clean wounds with a minimum of trauma repair begins soon after the injury and proceeds rapidly to complete healing whether with replacement of the original tis-

sue or with substitution of fibrous or scar tissue. The presence of suppuration retards the healing process. The age and the nutrition of the patient also influence the rate of healing as does the nutrition to the area of the wound. In well vascularized areas such as the face wounds heal with much greater rapidity than in a region with a small blood supply. When the blood supply of an area is affected by one of a number of vascular lesions resulting in a diminished blood flow the wounds may show little or no tendency to heal. In the past it was generally accepted that profound anemia retarded wound healing but according to Besser and Ehrenhaft⁷ anemia in itself does not inhibit wound healing. Severely anemic patients often have protein and vitamin deficiencies which probably account for the poor wound healing observed. It follows that any mechanical restriction of the arterial blood supply will also interfere with healing. Too tight bandages, pressure from splints or pads, excessive suture tension and tension from hemorrhage within the tissues are some of the more common mechanical causes of non healing.

The biological factors which influence wound healing have received considerable attention during the past few years. The excellent review by Arey⁸ on wound healing indicates how many factors may influence the process. Lanman and Ingalls⁹ have shown that vitamin C deficiency may cause a marked retardation in healing.

Surveys by Holman⁵ Rinehart⁶ and others have shown that many persons do not have an optimum vitamin C level. In the group of medical students studied by Holman 26.6 per cent had a vitamin C plasma level which was within the range in which the symptoms of scurvy have been observed. A very low level of plasma vitamin C is the rule in many surgical patients especially those with chronic infections, carcinoma and peptic ulcer.

Hardin⁷ among others has reported that vitamins A and D in the form of cod liver oil stimulate wound healing. Brush and Lam⁸ in a controlled experiment were unable to demonstrate any beneficial effect upon wound healing which they could attribute to the local application of vitamins A and D. If there is evidence or reasonable

suspicion of deficiencies of vitamins A and D it would seem in the light of present knowledge that to obtain any possible effect upon wound healing the most direct attack would be to administer these vitamins systemically rather than locally.

Protein is necessary for adequate wound healing. A protein deficiency retards fibroblastic proliferation whereas adequate protein stores and a high protein diet accelerate fibroplasia. Thompson, Ravdin and Frank⁹ found that 72 per cent of the wounds of hypoproteinemic animals either failed to heal or disrupted. In a study of wound disruption in patients Hartzell, Winfield and Irvin¹⁰ found either a protein deficiency or a vitamin C deficiency or both. Evidence is gradually accumulating which shows that a serious protein deficit is more often present than a vitamin C deficiency. Without adequate building material satisfactory repair cannot take place.

Fluid and electrolyte balance are also important factors in wound healing. According to Herrmannsdorfer¹¹ alkalosis inhibits and acidosis apparently favors wound healing. It is of the utmost importance that the surgeon keep his patient in proper fluid and electrolyte balance.

The widespread use of sulfonamide compounds has raised the questions as to whether or not these substances interfere with wound healing. Systemically administered sulfanilamide and sulfadiazine do not interfere with normal wound healing of the abdominal wall and the stomach according to Zintel and his associates.¹² Taffel and Harvey¹³ also found no inhibition of wound healing of the stomach when sulfanilamide was so administered. Bricker and Graham¹⁴ on the other hand reported that systemically administered sulfanilamide did impair wound healing.

In regard to the local use of sulfonamides it must be recognized that large amounts do interfere with wound healing. This is obvious because dead spaces are created which lead to serum collections and because clots or concretions are formed when the less soluble sulfonamides are employed. When used in amounts of 0.1 Gm. per square inch of wound surface Zintel¹⁵ found that sulfanilamide did not interfere with normal wound healing whereas sulfathiazole in equal amounts did impair the tensile strength of

healing soft tissue wounds in animals Key and Burford¹⁸ found that sulfanilamide did not interfere with healing of experimental fractures

Splinting of a wound in most cases favors healing since it prevents destruction of new tissue by motion or tension Careful suturing of an operative wound holds the tissues in apposition during repair Complete rest is essential in nerve and tendon repair and this is obtained in part by adequate suture and in part by immobilization Occasionally repair progresses to a certain point and then ceases but may be reinitiated by irritation This is sometimes true in callus formation

tion of the scar During the lag phase the serum and blood form a coagulum which is simply a fibrin network which contains leukocytes and red blood cells As the two surfaces of an incision thus become glued together some of the coagulum may exude from the surface of the wound to form a crust or scab Some lymph exudes into the wound but this is usually of small amount in a cleanly incised wound The phase of fibroplasia begins from three to five days after injury The fibroblasts begin to divide by mitosis and grow along and into the fibrin network formed during the lag phase The fibrin network is gradually absorbed by

Fig 2—Photomicrograph of a section of a healing wound in a rabbit's tongue Observe the fibrin in the upper part of the picture the fibroblasts at A and the capillary loop growing in B $\times 80$

after fracture when there is delayed or non union further callus may form if there is some friction between the ununited ends

Healing by First Intention—The ideal toward which every surgeon strives is to obtain primary healing of a wound without delay and without infection As a result of the incision there is injury to the adjacent tissue cells with escape of tissue fluid which is believed to be the initiating factor in repair

The actual process of wound healing is familiar to every student of pathology The process is divided into three phases the first phase is the lag phase second the phase of fibroplasia and third the phase of contrac-

tion of the scar During the lag phase the serum and blood form a coagulum which is simply a fibrin network which contains leukocytes and red blood cells As the two surfaces of an incision thus become glued together some of the coagulum may exude from the surface of the wound to form a crust or scab Some lymph exudes into the wound but this is usually of small amount in a cleanly incised wound The phase of fibroplasia begins from three to five days after injury The fibroblasts begin to divide by mitosis and grow along and into the fibrin network formed during the lag phase The fibrin network is gradually absorbed by fibroblasts and macrophages Capillary buds are formed but in an incisional wound little new vascularization is necessary Soon the rapidly increasing fibroblasts and the accompanying blood vessels have filled the defect and restored the continuity of the tissue The new tissue so formed is bright red soft and friable and is called *granulation tissue* It is small in amount in the wound that heals by first intention It is during the phase of fibroplasia which begins between the third and the fifth day and continues to approximately the tenth day after injury that the wound strength is rapidly increased Epithelial cells proliferate to cover the wound Finally during the phase of contrac-

tion the fibrous tissue which results from the healing gradually contracts. Small new capillaries are squeezed until they are obliterated. This contraction continues for an indefinite period, often for as long as a year.

During the lag phase and the early part of the phase of fibroplasia, the strength of

tures has come from the work of Howes and Harvey.¹⁷

The surgeon must plan each incision so that the contraction of the scar will least distort and thereby least interfere with the function of the surrounding tissues. In a large wound in which the edges are not

Fig 3—A later stage in the repair of a wound in a rabbit's tongue. The fibrin is replaced by dense scar tissue, and most of the capillaries have been obliterated by its contracture. The epithelium has grown over the surface; $\times 460$.

the wound is very slight. The rapid ascent of the tensile strength curve from the sixth to the tenth day has great practical significance as regards the type of sutures used, and the stress thrown on the wound must be considered with this in view. Valuable information on the tensile strength of healing wounds and the tensile strength of su-

closely approximated, the closure of the defect is due more to the contraction of the fibroblasts than to the actual filling effect of the proliferating tissue.

Scar tissue is never as resistant to tension as normal tissue, and if present in any amount, it may prove to be a vulnerable point in any area subjected to pressure or

tension It is desirable therefore to have the least possible amount of scar tissue following an abdominal incision Occasionally even though the wound surfaces have been accurately approximated fibroplasia may continue until the cicatrix becomes the site of a new growth Instead of cessation of fibrous tissue formation as soon as continuity is re-established proliferation of fibroblasts continues with the resulting formation of a keloid

Healing by Second Intention—There are a number of factors which may inhibit or retard healing some of which have already been discussed If the loss of tissue

tissue Obviously there is more scar tissue present in these wounds the amount depending on the amount of tissue destroyed and the area to be restored Epithelization occurs on the surface as a rule only when the depths of the wound are filled with granulation tissue

An aseptic hematoma also may delay healing by the mechanical separation of tissue and when healing finally occurs a greater amount of fibrous tissue will be present Devitalized tissue from mass ligatures or from crushing by hemostats also will delay healing even in the absence of organisms, but too often this tissue forms

Fig. 4—Epithelium growing over granulation tissue. Note the exaggerated downward growth commonly seen where healing has been difficult

has been so extensive as to prevent accurate approximation or if infection develops primary union does not occur instead there is healing by second intention When a tissue defect is present the reactions of repair are similar to those observed in healing by primary intention but are greater and more prolonged in duration In an infected wound the extent and virulence of the infection determine the degree of retardation of wound repair In the presence of infection there is an outpouring of exudate and a migration of polymorphonuclear leukocytes into the wound This together with the tissue debris makes up the pus which is found in such a wound When the infection has been overcome the filling of the wound will proceed again by the formation of granula

a favorable site for infection Foreign bodies acting as tissue irritants likewise retard or inhibit healing

Healing by Third Intention (Secondary Suture)—Occasionally a wound is left open for some purpose the granulating surfaces being sutured together a few days later or after infection with delayed healing the granulating surfaces are approximated to hasten healing and to lessen the formation of fibrous tissue This then is known as secondary suture or healing by third intention

While this discussion has mainly concerned itself with repair of incised wounds there are many other types with which the surgeon must deal In a large denuded area the very size of the defect may defeat the

process of repair Epithelization from the peripheral epithelium will continue only for a certain distance and then a chronic ulcer may remain If the area to be covered is large new skin must be added usually by the use of skin grafts placed on the healthy granulation tissue If considerable scar tissue formation occurs at the periphery and base of a large surface wound the contraction of this tissue may so restrict the blood supply that further repair in the central portion of the wound ceases It may then become necessary to remove the fibrous tissue or to supply additional tissue by means of flaps or pedicle grafts

REPAIR OF SPECIAL TISSUES

Epithelium—Epithelium has marked powers of regeneration as a rule In the skin and mucous membrane there is rapid repair and often complete restoration of the typical cellular arrangement

Muscle—As in certain other tissues cells of the muscle do not take part in the process of repair Outgrowths from the fibrous tissue of the muscle sheath and the partitions between groups of muscle fibers form the new fibrous tissue which unites the separated muscle All necrotic or severely damaged muscle in a wound should be removed because it will not be regenerated and its presence will only retard healing and increase the amount of the cicatrix Obviously the smaller the amount of scar tissue necessary to fill the defect the less interference will there be with function

Tendons—Tendons are made up mainly of parallel closely adjacent collagenous bundles Fibroblasts are the only cells present They have a very limited blood supply the small vessels being carried in the mesotendon a fold passing from the sheath to the tendon much like the intestinal mesentery The mesotendon may be absent in certain locations or it may be a rudimentary structure When tendons are divided the mesotendon may stretch and form a bridge between the retracted ends

After division or rupture of a tendon exudate and blood fill the space between the ends A moderately rapid growth of granulation tissue replaces the exudate and soon fibroplastic proliferation into the granulation tissue occurs The growth about the

ends of the tendon frequently resembles in shape the callus formation in a fracture Shortly the new tissue becomes avascular and takes on the characteristic tendinous form The increase in the length of the tendon under such circumstances frequently leads to loss of function

When the tendon sheath also is divided the structures must be carefully sutured or in all probability normal healing will not take place, instead scar tissue will form which penetrates to the surrounding tissue and results in loss of function To avoid this the tendon should be carefully sutured or if the retraction has been too great or a part of the tendon lost so that the ends cannot be approximated the gap should be bridged by tendon grafts or tendon plastic procedures In this manner firm union will occur by the usual method of tendon repair

In a discussion of tendon repair the excellent article by Mason and Shearman¹⁸ is of interest

The tendon itself takes an important part in healing but because of its scanty blood supply and the very nature of its tissue it begins its proliferation later and it progresses more slowly than ordinary connective tissue This tardiness of tendon response is compensated to some extent by the early response of the sheath

To take advantage of tendon proliferation one must carefully avoid traumatizing the tendon and especially must one avoid injury to the ends of the tendon that one wishes to bring together These studies have shown that the tendon ends start to proliferate about the fourth or fifth day after suture and to send out bands of cells and fibrils into the gap tissue beyond If the tendon is injured or if it is stripped of blood supply necrosis is likely to occur and delay the process It is shown by histologic study of healing tendon sutures that union is effected first by proliferation of the sheath tissues This union serves to reestablish continuity in a few days After the fourth or fifth day the tendon itself begins to proliferate and to send cells into the callus and if the gap is not too great it may be bridged by tendon cells in about two weeks After the sheath has served its purpose of splinting the first union it begins to become more lax and areolar and in a successful suture to take on again its original function of serving as gliding tissue

Bone—While the structure of the bone involved modifies the form of repair the same principles of healing are followed as in other tissue After a fracture which usually is associated with more or less laceration of the periosteum and trauma to the surrounding soft parts a clot forms between the ends of the fractured bone After this

there occurs an exudate from the vessels and swelling of the surrounding tissue. The typical proliferation of connective tissue from the endosteum, the periosteum and the haversian canals and the formation of epiphyseal buds follow rapidly.

Thus far repair has been much the same as in any tissue. The cells of the periosteum and the endosteum however have osteogenic properties and from these osteoblasts new bone tissue forms. The clot is absorbed and replaced by vascular and new osteoid tissue. The osteoblasts have fibrils which ex-

rapidly of healing. Immobilization is essential though if the injury is near or into a joint it is necessary by early motion to prevent permanent restriction of joint motion.

Gastrointestinal Tract—After division of the stomach or of the intestine the portion to be closed or the parts to be anastomosed must be sutured in such a way that serosa will unite with serosa and mucosa with mucosa. The importance of careful approximation of serosal surfaces cannot be overemphasized because it is only by careful serosal suture and the subsequent

Fig 5—Invasion of callus by osteoblasts

tend in all direction and these fibrils as well as the cells themselves become embedded in a homogeneous matrix. When calcium salts are deposited within the osteoid tissue it becomes a spongy osseous tissue—the *callus*. This calcium then undergoes partial absorption as new and finer bone is laid down within it. The superfluous external callus is all absorbed until the normal contour of the bone is restored. In long bones with a vascular marrow healing occurs more rapidly than in flat bones. Bones with little or no periosteum such as the carpal bones and the patella heal slowly.

Just as in soft tissue careful approximation of the ends of the fractured bone is important not only for the final structural and functional result but to increase the

rapid sealing of the wound with exudate that leakage of intestinal contents into the peritoneal cavity can be prevented. As soon as the serosal surfaces are sutured the exudate forms and effectively seals the union. As in other epithelial wounds this exudate is invaded by granulation tissue from the subserous connective tissue. Healing is more rapid than in other epithelial tissue. The united mucosa which has been inverted into the lumen by the suture undergoes more or less necrosis along the suture line but as this sloughs off granulation tissue forms and is then replaced by new mucous membrane which may in every way resemble the normal tissue.

The site of a carefully made intestinal anastomosis may show very little scar tis-

sue and little or no contraction. Since the blood supply of the intestine is through vessels from the mesentery which run circularly not longitudinally in the wall of the intestine it is obvious that healing will not occur and necrosis will develop in an area that is stripped of its mesentery beyond the limits of the anastomosing vessels.

Nervous Tissue—Nerve cells which have been destroyed are not replaced. However the various parts of a cell may regenerate if the cell itself remains alive. When a peripheral nerve is divided the axon will grow in a peripheral direction and function will be restored. As in other highly specialized tissue the connective tissue which grows more rapidly than the specialized tissues may surround it and check further growth.

II. BACTERIOLOGY OF SURGERY

RELATIONSHIP OF BACTERIOLOGY TO SURGERY

WHY SHOULD A SURGEON BE INTERESTED IN BACTERIOLOGY?

The Contamination of Operative Wounds—Every operative wound made by a surgeon is contaminated with bacteria. Before the time of Pasteur and Lister the vast majority of surgical wounds became infected. This effectively limited the scope of surgery to emergency measures on superficial easily approachable lesions. The inner parts of the body were unapproachable because of the fatal outcome of any infection within them. Thanks to these great geniuses ways and means have been found by which we prevent the occurrence of wound infections. All of the thousand and one steps in the sterile technic which have been elaborated are directed toward minimizing the contamination of the operative wound. The surgeon must know the sources from which these organisms come and must develop his sterile sense to such a point that he will not be responsible for any contamination which might be avoided.

Surgical Infections—From one third to one half of a surgeon's practice concerns lesions which have been contaminated with or infected by bacteria before the patient comes to him. Any one who visits a general hospital and makes the rounds from bed to bed in any general surgical ward will find every second or third bed occupied by the victim of an infection which was established before he entered the hospital or by the victim of an injury with a potentially infected wound. Any one who visits the surgical outpatient department finds an even larger proportion of infections among the patients who are treated there. The surgeon must therefore know how to treat lesions which have been produced by bacteria or which have been contaminated by them.

Postoperative Infections—Bacteria are frequently responsible for serious postoperative complications. As a result of the anesthetic or of the operative procedure itself

there are certain disturbances of the normal physiology of the respiratory, alimentary and urinary tracts. At such times bacteria may invade the physiologic interior of the body or in his efforts to restore the normal physiology the surgeon or his aides may introduce bacteria into regions which are normally free from them. The surgeon must know how to avoid these physiologic disturbances and how to prevent the contamination of clean tissues during or after operation.

WHY IS STERILE TECHNIC NECESSARY?

Before and After Lister—In this present day and age any one who attempts to perform surgical operations conforms more or less rigidly to certain rules of procedure known as sterile technic. Just so far as these rules are followed infections of operative wounds are reduced just so far as these rules are ignored infections of operative wounds are increased. Only those whose practice extends back over sixty years have any conception of the state of affairs before the various steps in sterile technic were adopted. However vivid word pictures have been left for us to read and frequent reference should be made to them lest we forget what would surely be the outcome if we abandoned the practices which we now employ.

Nowadays a study of wound infections in clean cases gives no adequate picture of what occurred before 1875 but it reveals the fact that there are still sources of wound contamination which have not been eradicated. Doors do not have to be opened very widely for bacteria to enter from a number of different directions and the modern surgeon must be on guard constantly to keep every means of entrance closed.

Present Day Sources of Contamination of Clean Wounds—If one were to ask the average surgeon how often his clean wounds become infected he would probably answer, "Very seldom, not once in a hundred times" or "I haven't had an infection in

years" Unless that statement is backed up by actual records the chances are that that would be an understatement of the facts. In most hospitals careful records of wound healing are not kept. In some hospitals however such records are kept and analyzed at frequent intervals in order to keep the staff keenly alert to prevent wound contamination and to improve the record of wound healing. In one such hospital where the question has been studied carefully for eighteen years where the records have been scrupulously kept for every clean case in which an operation has been performed and where the condition of the wounds at subsequent dressings has been consistently scrutinized the following facts have been brought out:

a General impressions regarding wound infections are not accurate. The actual number will vary from 5 to 20 per cent or more of all clean cases. Of these from 1 to 5 per cent will be serious resulting in pain, fever, suppuration, weakness of the wound, disruption or hernia, prolonged hospitalization and occasionally death. The others may be called trivial but they are annoying to the patient and usually delay his departure from the hospital. In the average case of infection the patient must remain in the hospital just twice as long as the patient in whom infection does not occur.

b The organisms which have been cultured from wound infections in clean cases give a clue to their origin.

Over a period of eight years in the Presbyterian Hospital, New York, while there was complete masking of the nose and throat of all persons entering the operating room, a record was kept of the various organisms found in the inflammatory exudate of clean wound infections. The percentage of incidence of these organisms is shown in table 1. It is seen that the staphylococci composed by far the most common group occurring in two thirds of all the infections. The hemolytic *Staphylococcus aureus* was found in almost one third of all the serious infections and the *Staphylococcus albus* was the chief offender in the trivial infections being present in almost two fifths of the cases. The hemolytic and non-hemolytic streptococci were found in 4 and 5 per cent, respectively. The hemolytic variety was more serious than the non-hemolytic and both of them were found more often in serious than in trivial infections. *Bact. coli* and *Bacillus proteus* were somewhat more likely to produce serious than trivial infections and *B. pyocyaneus* while not occurring so frequently were invariably serious. On the other hand *B. subtilis* and the diphtheroid bacilli

which are ordinarily not considered pathogenic occasionally caused trivial infections and when found were frequently in pure culture. Among the others the only organism of importance was *C. urechei* which occurred once in an amputation stump and was probably present in the gangrenous foot requiring the amputation.

Where did these organisms come from? We know that staphylococci are frequently found on the skin and probably frequently lodge live and perhaps grow in the sebaceous and the sweat ducts and in the hair follicles. They are also commonly found in the air. When blood agar plates have been exposed in an operating room while an operation was in progress as many as one to two colonies of bacteria per minute of exposure have appeared after the plates have been incubated. This would mean that from 30,000 to 60,000 bacteria are deposited from the air on the sterile field during the average operation. Staphylococci represent a large proportion of these organisms. If plates are exposed in an operating room when no operation is in progress and no one enters the number of colonies is reduced to 10 per cent of the above figure. They are almost invariably present also in the human nasal passages and are discharged during expiration. These organisms occasionally also contaminate the operating room tables, the beds or the floor when the pus from infected cases caused by them is allowed to escape at the time of operation. Likewise the floor of the operating room may be contaminated with staphylococci from material which is brought in on street shoes and which when dried may be carried about on currents of air.

Streptococci are not commonly found on the skin but are occasionally found on blood agar plates exposed to the air. The hemolytic variety is frequently found in the throat and more rarely in the nose. The non-hemolytic streptococci are invariably present in the throat and are frequent in the nose. Both staphylococci and streptococci are often picked up by the hands and clothing of doctors and nurses when landing or dressing patients. Both streptococci and staphylococci are easily killed by relatively low degrees of heat and could hardly escape death in the autoclave or instrument sterilizer even when too brief or inadequate temperatures fail to kill many other organisms. For that reason supplies and instruments and catgut may be practically eliminated as possible sources of these organisms unless they have been contaminated from other sources after sterilization.

Bacillus subtilis and the diphtheroid bacilli are of little importance although *B. subtilis* which produces a resistant spore is an excellent test organism for the adequacy of sterilization. Both of these groups of bacteria are frequently found on the skin and on blood agar plates exposed to the air.

Bacterium coli, *Bacillus proteus* and *B. pyocyaneus* are most commonly found in the intestinal tract and are therefore frequently picked up by the hands of doctors and nurses. They are occasionally found on plates exposed to the air but not as frequently as the other organisms.

How Can We Minimize the Contamination of the Operative Wound by These

TABLE 1—INCIDENCE OF THE VARIOUS ORGANISMS FOUND IN CLEAN WOUND INFECTIONS FOR EIGHT YEARS OF COMPLETE MASKING AT OPERATION

Organisms	Serious per cent	Trivial per cent	Total per cent
Hemolytic streptococcus	9	2	4
Non hemolytic streptococcus	7	4	5
Hemolytic <i>Staphylococcus aureus</i>	30	16	22
Non hemolytic <i>Staphylococcus aureus</i>	13	14	14
<i>Staphylococcus albus</i>	19	38	31
<i>Bacterium coli</i>	7	6	6
<i>Bacillus proteus</i>	3	2	3
<i>Bacillus pyocyaneus</i>	4	0	1
<i>Bacillus subtilis</i>	4	7	6
Diphtheroids	0	6	4
Others	2	4	4

Organisms?—It would seem that the chief sources of contamination are, in the order of their importance (1) the skin of the patient, (2) the noses and throats of persons in the operating room (3) the hands of the operating personnel (4) the air of the operating room and (5) the instruments and materials

1 Contamination from the skin of the patient may be minimized but with our present knowledge it can not be entirely prevented. No antiseptic yet devised is able to destroy all of the bacteria deep down in the hair follicles and sebaceous glands. During the operation some of these are undoubtedly cast out in the secretion of the skin glands. When the scalpel cuts through the skin it carries some of these organisms into the wound. If the cautery knife is used to make the incision and if the edges of the skin are then fastened with Michel clips or towels these sources of contamination will be reduced. Sterilization of the skin seems to be the weakest link in the chain of sterility technique and careful search should be continued for a more penetrating and more effective antiseptic. In our laboratory Kraissl and Cimotti have experimented on the skin of rabbits with all the advocated skin antiseptics including iodine (alcohol and water soluble), mercurochrome, metaphen, merthiolate, acriflavine, gentian violet, methyl violet and brilliant green, hexyl resorcinol, sodium hypochlorite and azochloramide. When bits of skin are snipped out after contact with these preparations, water-soluble iodine solutions consistently give the highest percentage of sterile cultures but even iodine does not give more than 60 to 70 per cent sterility, leaving much to be desired.

2 Contamination of the wound by organisms from the nose and throat may be minimized by completely covering the nose and mouth with an impermeable

mask or a four ply fine meshed gauze mask which will catch the droplets which are invariably expelled during coughing, talking or breathing. A helmet should cover the head and neck. This will serve to divert air currents during expiration down into the gown. These currents might otherwise carry bacteria around the mask and on to the sterile field.

3 Contamination from the surgeon's hands may be minimized by prolonged scrubbing with soap and hot water to remove the top layers of keratinized skin and the accompanying bacteria and then by washing in an antiseptic solution. It has been demonstrated that a mixture of chloride of lime and sodium carbonate is effective for this purpose. However, this is irritating to the skin of some persons and less active substances may have to be employed for example, bichloride or biniodide of mercury (1:1000) [70 per cent alcohol—Ed].

4 Contamination from the air may be minimized by limiting the number of persons entering the operating room before as well as during the operation by minimizing the opening and closing of doors and the activity within the room during the operation by covering as much of the sterile field as possible with canopies by covering the hair, the nose and mouth and the feet of all those who enter the operating room by filtering the air either before it enters the room or by circulating it through a filter in the room by having as few as possible dust-collecting objects in the operating room and by frequently cleaning the walls, ceiling and floor. Studies by Wells¹⁴ and also by Hart¹⁵ have demonstrated the possibility of minimizing air contamination by the use of ultraviolet radiation in the operating room. Suitable apparatus is now available which releases a high percentage of rays from the bactericidal zone of the ultraviolet spectrum the intensity of which can be accurately measured. Kraissl, Cimotti and Meloney¹⁷ have shown that effective intensities can be obtained which are not injurious to the tissues

but which will reduce air contamination to one tenth or one twentieth of the amount normally found in the operating room

5. Contamination from autoclaved supplies should be absolutely prevented. If an adequate vacuum is used before the steam is introduced there should be no difficulty in destroying all bacteria (fifteen minutes' vacuum and forty-five minutes' sterilization at from 18 to 20 pounds of pressure is a safe standard). If less time is given for the preliminary period of evacuation, a longer time will be required for sterilization. The timing device invented by Walter²⁴ for keeping the autoclave locked until sterilization is complete is an added safeguard which is of considerable value. The boiling of instruments is perhaps the most efficient method of killing the bacteria on them and if sufficient time is given—from five to ten minutes—one need have no fear of contamination from these sources. A few pathogenic strains of spore-forming organisms have been reported on which will resist boiling for fifteen to twenty minutes or longer but for all practical purposes the time just mentioned will be adequate. Sharp instruments such as knife blades, scissors and needles are generally and properly sterilized by prolonged soaking in a non-corrosive antiseptic such as the Bard Parker solution. Instruments and sponges constantly transfer into the wound organisms which have dropped on them from the air or which have been transferred from other contaminated objects. They thus act as secondary rather than primary sources of contamination.

ESTABLISHED SURGICAL INFECTIONS

Definitions.—Infectious diseases are those disorders of the animal body resulting from the entrance of micro-organisms into the tissues where they can live, grow, multiply and carry on their metabolic processes. Surgical infections are those which, according to the best medical opinion, should be treated by operative means. The factors which make an infectious disease amenable to surgical therapy depend on whether the lesion is likely to resolve spontaneously or is likely to produce necrosis of tissue or a localized collection of purulent exudate which can be excised, incised or drained with relatively little harm to the body as a whole. If, with a minimum of injury, the whole or a large part of the focus of infection can be removed, a surgical procedure is warranted, but the good that is accomplished must outweigh the harm that is done. For example, an acutely inflamed appendix, a chronically infected gallbladder or a pyonephrosis may be excised; an abscess of a lymphatic gland may be drained, and cellulitis of the neck which will probably produce edema of the glottis may be incised. On the other hand, surgical procedures are not warranted if the

infection is one which ordinarily subsides spontaneously, such as pneumonitis or phlebitis; if it is one which responds to medication, as, for example, a syphilitic lesion, or if it is one which yields to rest and sunshine, like certain tuberculous processes; or if there has been little destruction of tissue, as in a low grade cellulitis, or if the process is generalized, as in miliary tuberculosis. Similarly, if the lesion is inaccessible because of intervening parts, as in bronchial lymphadenitis, or because its exact location is not known, as in many cases of septicemia, or because it involves some essential organ, such as the valves of the heart, surgical procedures in their present stage of development are contraindicated because they would do more harm than good. Organisms which produce lesions in the body which warrant surgical treatment are those which either cause local death of tissue or cause the exudation of leukocytes in large number, in other words, necrotizing or pyogenic organisms.

What Organisms Produce Surgical Infections?—Most of the micro-organisms which have been found to exist in nature are of little concern to those who are solely interested in human infectious diseases. A great host of organisms, however, are of vital interest because they make life possible by completing the cycle of physical and chemical processes which cause the disintegration of dead animals and plants into the simple chemicals which plants require for their own synthesis. The plants are in turn consumed by and make possible the growth of animals and man. Of the relatively small group of bacteria which are pathogenic for man, a still smaller number produce surgical diseases. These will be considered in the following order:

I Aerobic bacteria

A Aërobic cocci

(I) Gram positive

(A) Streptococci

1 hemolytic

2 non-hemolytic

(B) Staphylococci

1 aureus

2 albus

(C) Pneumococci

(II) Gram negative

(A) Gonococci

B Aerobic bacilli

(I) Gram positive

- (A) *Bacillus tuberculosis*
- (B) *B. anthracis*
- (C) *B. löffleriae*
- (D) *Diphtheria bacilli*
- (F) *B. subtilis*

(II) Gram negative

- (A) *Bacteri coli*

In the following paragraphs a brief account is given of the surgical infections caused by these various organisms. For the morphologic and cultural characteristics of these bacteria the reader is referred to text books of bacteriology.

I AEROBIC BACTERIA

A AEROBIC COCCI

(I) Gram Positive Cocci (A) Streptococci—The only significant division of this group is based on the lytic action of the organism on red blood cells. Streptococci which produce hemolysis are in general of considerable virulence and those which do not are relatively avirulent.

1 *Hemolytic Streptococci*—Previous to 1935 hemolytic streptococci were the cause of most of the fulminating cases of blood poisoning. The discovery and rapidly spreading use of sulfanilamide however have not only saved many patients with

septicemia who otherwise would have died but the control of local infections due to this organism in the early stages has in recent years often prevented the development of septicemia. This has rendered infections with hemolytic streptococci less menacing than formerly and the non hemolytic streptococci which sulfanilamide does not control have become relatively more important. They are frequently found in the throats of normal persons especially during the late winter and early spring months and are widely disseminated from that source so that many persons acquire the organisms when in crowded places and pass them on to others through the medium of handkerchiefs, hands or droplets discharged from the nose or mouth with breathing or coughing. Streptococci probably do not live for a long time outside the animal body but when they are fairly directly transferred from one human environment to another small numbers are able to produce disease.

Hemolytic streptococci enter the body most often through an accidental wound such infections being much more frequent in the later winter and early spring than at other times of the year. Just how the organisms live, grow and spread in such a wound will be discussed later. Suffice it to say here that they usually produce cellulitis in such wounds and frequently cause lymphangitis, lymphadenitis, suppurative phlebitis and septicemia or they may very rapidly produce extensive gangrene of the skin.² When streptococci persist in the blood stream because of the presence of an overwhelming distributing focus of infection they may settle in the spleen, liver, kidney or bone marrow, gain a foothold and produce other metastatic abscesses. In children they frequently localize in joints particularly the hip joint or in the neighboring epiphyses.

Hemolytic streptococci may invade the body through the throat and tonsils and spread to the cervical lymph glands where they produce adenitis which is frequently accompanied by high fever and profound intoxication. Such an infection may persist for weeks for the glands are slow to resolve or slow to liquefy and form an abscess. The organisms may produce diffuse cellulitis of the neck which may spread to the glottis and by a rapidly developing edema threaten

suffocation Hemolytic streptococci are frequently found in cases of acute peritonitis. Usually in such instances there is a history of previous upper respiratory infection. It is possible to cultivate the organisms from the blood in many of these cases. Hemolytic streptococci may also enter the body through the lungs producing pneumonia and suppurative pleurisy. Hemolytic streptococci are by far the most common organisms in

pathogenic strains from human sources in a single group by the employment of a precipitin test. Apparently the differences depend not so much on the particular type of hemolytic streptococcus as on the portal of its entry into the body and the resistance or susceptibility of the local tissues of the host.

2 *Non Hemolytic Streptococci*—In the production of surgical infections there is

Fig 6—*a* Staphylococci from broth culture $\times 1500$ *b* hemolytic streptococci from blood broth culture $\times 1400$ *c* round-end spore-forming gram-positive bacillus *C. tetani* from old cooked meat culture medium $\times 1400$ *d* aerobic oval spore-forming gram-positive bacilli *B. anthracis* from agar slant $\times 1400$ *

suppurative tenosynovitis. They are almost always introduced through a wound of the tendon sheath such as is made by a pin prick through a flexion crease.

The clinical manifestations of the different diseases produced by the hemolytic streptococci are so varied that many attempts have been made to find some cultural or biologic activity to account for the differences, but most of these artificial classifications have been without clinical significance, with the exception of Lancefield's.⁴ She has been able to place almost all of the

little difference between the streptococci which form green colonies on blood agar plates and those which have no effect on the red cells. Such organisms produce lesions which are even more varied in their clinical manifestations than those produced by the hemolytic streptococci. They are usually associated with the respiratory or intestinal tract. Non-hemolytic streptococci are normal inhabitants of the mouth and are present but are less numerous in the

*Meleney: The Bacteriological and Immunological Aspects of Surgery. In Nelson's Loose-Leaf Surgery.

nasal passages. They are frequently the chief offenders in the formation of abscesses around the teeth or of abscesses in the cervical lymph glands following dental infections. They are apparently able to resist the destructive action of the gastric juice, for they are frequently present in the upper duodenum; and when a perforation develops in that portion of the intestinal tract, they

clearcut. They may frequently be cultured from the contents or the wall of an inflamed gallbladder and share with *Bact. coli* and *Bact. typhosum* the responsibility in the production of infectious cholecystitis and cholelithiasis. In association with *Bact. coli* they may also produce liver abscesses. Apparently they have a symbiotic role in the severe infection known as Vincent's angina, in which

are frequently found in pure culture in the peritoneal exudate. They are present in the intestinal tract in increasing numbers from above downward and are commonly found in the peritoneal exudate when the appendix perforates. They may occasionally pass through an inflamed appendix wall without perforation.* They are found in large numbers in the exudates in cases of ulcerative colitis, but it has not been proved that they are the etiological factors. Similarly, it has been claimed that they produce gastric and duodenal ulcers, but the evidence is not

the spirochetes and fusiform bacilli from the mouth play an active part. Likewise, they are frequently found in infections which follow animal bites or human bites. Like the hemolytic variety they may contaminate accidental wounds and cause infections in them.

(B) *Staphylococci*.—Surgical infections caused by staphylococci are more numerous than those caused by streptococci, but in general they are less serious. Staphylococci

* Meleney. The Bacteriological and Immunological Aspects of Surgery, in Nelson's Loose-Leaf Surgery

have been significantly classified according to their pigment formation and less significantly according to their power to hemolyze blood

Staphylococci are more resistant to control with the sulfonamide drugs than are the hemolytic streptococci partly owing to the fact that they characteristically produce early necrosis of tissue which interferes with the action of these drugs. Sulfanilamide has practically no effect on these organisms. Sulfathiazole on the other hand has been able to reduce the mortality of staphylococcal septicemia to an appreciable degree and probably has been able to prevent septicemia in severe local infections with these organisms.

Bacteriophage—Staphylococcal infections frequently respond to the local application or general administration into the blood stream of staphylococcus bacteriophage. The *Staphylococcus aureus* group of organisms constitute one of the few groups which respond favorably to this type of therapy because phages are available which are potent against a wide variety of strains. Success depends upon using a phage which is potent for the organism causing the infection preferably one which passes the double potency test that is it will not only clarify by lysis a turbid suspension of organisms in liquid medium but will not permit growth when the cleared culture is transplanted to a blood agar plate. In the treatment of local staphylococcal infections it should be administered daily with a blunt hypodermic needle into the center of the lesion. Usually within twenty-four hours there is subsidence of the spread and thereafter rapid liquefaction of slough and resolution of the infection occur obviating the necessity for surgical treatment. Tissue which has been killed prior to the application of the phage will of course have to liquefy and come away either as a core (slough) or as pus. Occasionally this is facilitated by a small incision.

In the treatment of staphylococcal septicemia "doubly potent" phage should be given intravenously as soon as the diagnosis is made starting with 1 cc and increasing by 1 cc increments at hourly intervals up to 5 cc thereafter with a cc increase every four hours up to 20 cc. Treatment should

be continued until the blood culture has been negative on alternate days and the temperature is maintained below 102° F.

Penicillin—In 1929 Fleming reported inhibition of growth of staphylococci on an agar plate by the action of some widely diffusing substance produced by the mold *Penicillium notatum*. Since then the extract from the products of this organism has been purified and made available for clinical use. Its chief value has been demonstrated to be in the control of pure staphylococcal infections including septicemia except in cases in which such infection has become established on the heart valves. Certain other organisms are susceptible to penicillin including most of the gram positive but in surgical infections its outstanding benefits have been obtained in staphylococcal lesions and field in which the sulfonamides have been disappointing. Penicillin has a further advantage over the sulfonamides in that it is almost completely lacking in toxicity. Furthermore its action is not inhibited by the presence of broken-down tissue, blood or pus. Its chief shortcoming in the treatment of surgical infections is the fact that it is inhibited by the presence of many of the gram negative bacilli which may limit its usefulness for war casualties and civilian wounds.

Staphylococcus aureus—Organisms of this type are found commonly on the skin and may be able to live and grow in the ducts of the sweat and sebaceous glands. They are frequently present in the nasal passages but more rarely in the mouth and alimentary tract. Apparently they can survive for a long time on dust particles in the air. They produce a yellowish brown pigment in the colony when grown on solid artificial media and vary considerably in their hemolysis on blood agar plates. *Staphylococcus aureus* is the common organism present in localized inflammatory processes of the skin such as furuncles and carbuncles. It occasionally produces an abscess around a tooth and is almost the sole cause of suppurative parotitis. Rarely yellow staphylococci enter the body through the lungs and produce pneumonia and empyema but this is usually a sequela of septicemia. They exceed streptococci in the frequency of causing clean wound infections probably be-

cause they are invariably introduced from the surface of the skin itself. There is no seasonal incidence of staphylococcal infections as there is with streptococcal infections. From infected wounds they frequently spread via the veins or lymphatics into the general circulation and produce septicemia with metastatic abscesses in various organs or tissues of the body. In such cases either suppurative thrombophlebitis of the small vessels in the wall of the local lesion or in the neighboring veins or lymphatics or vegetative endocarditis is usually found at autopsy. Staphylococci seem to have a special predilection for bone especially in young children. They may enter the body through a pimple or a trivial wound and produce a violent reaction resulting in extensive destruction of the bone marrow cavity.

2. *Staphylococcus albus*.—These organisms produce white colonies on agar plates which may or may not be hemolytic. They are extensively distributed in nature being found in the same localities on and in the human body as *Staphylococcus aureus*. Usually the lesions produced by them are milder than those caused by the yellow staphylococci. These organisms are most frequently found in small pimples and boils and in the trivial infections which occasionally occur in clean operative wounds. They rarely produce septicemia or osteomyelitis.

(C) *Pneumococci*.—The surgical diseases produced by this group of organisms are generally associated with either a pleural or a peritoneal infection. With less rapidity than the streptococci these organisms pass through the lung and infect the pleural exudate which develops to a variable degree in practically all cases of pneumonia. Frequently this pleural exudate remains sterile but if pneumococci can be cultured from it the condition generally develops into a surgical rather than a medical problem. Then a careful study of the individual case is required in order to decide whether and when to use surgical measures for relief. From the pleura pneumococci may spread to the pericardium and there produce a suppurative process which will require surgical therapy. When the organisms invade the blood stream they not infrequently localize in the joints or in the meninges. The former condition requires surgical treatment and the

prognosis is good but localization in the meninges was previous to the advent of sulfapyridine almost invariably fatal. This drug was soon found to have an almost miraculous curative effect on pneumococcal infections not only of the lungs but of the meninges. Sulfathiazole has more recently been found to be able to duplicate these results in pulmonary but not in meningeal infections due to the pneumococci. In a few cases an attempt has been made to introduce a specific antipneumococcus serum into the ventricles by operative means but success in such a procedure is rare.

Surgeons are particularly interested in pneumonitis following an operation. This is more likely to occur in a patient who has recently had a cold than in one who has not. It is also more common following upper than following lower abdominal operations. Apparently a number of factors—mechanical and chemical as well as infectious—are at play in the production of these lesions. Frequently a plug of mucus blocks a bronchus and produces an atelectatic area which becomes susceptible to bacterial infection. The lack of aeration in the bases of the lungs due to pain on deep breathing after an upper abdominal operation favors the closure of the small bronchi in the lower lobes. Cutler and Hunt¹ however have stressed the importance of the role of emboli which come from the operative field and produce small pulmonary infarcts which are subsequently infected. The importance of postoperative pneumonia has appreciably decreased since the advent of sulfapyridine and sulfathiazole.

Since pneumococcal infection of the peritoneum is four times as prevalent in females as in males the fallopian tubes have been considered to be the portal of entry. However some of these cases follow frank pneumonia and then the source of infection is almost certainly extragenital. Occasionally an ovarian cyst becomes infected with pneumococci. Here the portal of entry is uncertain.

(II) *Gram Negative Cocci*. (A) *Gonococci*.—The activity of these organisms comes within the scope of surgery largely through errors in diagnosis. Operations are often performed in cases of acute peritonitis suppurative arthritis suppurative teno-

synovitis or epididymitis because it is impossible to tell before a culture of the exudate has been made whether the infectious agent is the gonococcus or some other organism. Since gonococcal lesions usually subside spontaneously, these operations are futile and probably harmful although in many instances they are justifiable. The response of these infections in both acute and chronic forms to sulfathiazole has largely taken them out of the field of surgery.

Penicillin is particularly potent against the gonococcus even when the organism has become resistant to sulfathiazole or sulfadiazine. A few (five or six) injections in intramuscularly of 10 000 to 15 000 units every three hours will rid the genital tract of these organisms rapidly and usually permanently. Occasionally a second series of injections must be given if there is recurrence of symptoms. When joints are involved penicillin associated with fever therapy is required to control the infection.

B. AEROBIC BACILLI

(I) Gram Positive Bacilli (A) *Bacillus tuberculosis* from a surgical point of view is by far the most important of the aerobic bacilli. It may attack any organ or tissue of the body and in that respect is more ubiquitous than any other organism. Fortunately in this country surgical tuberculosis has gradually become more and more rare as a result of improved hygienic conditions and an appreciation by the patient developed by popular education of the importance of treating the disease in its early stages.

The tubercle bacillus usually enters the body through either the respiratory or the alimentary tract and frequently lodges in the cervical and mesenteric lymph glands. In the former instance the tonsils are frequently found to be infected and require surgical removal.

Milk as a source of the bovine type of tubercle bacillus has been practically eliminated in many states by the testing of herds and the destruction of tuberculous cattle.

Twenty five years ago it was common surgical practice to remove tuberculous cervical lymph glands by excision. Today this procedure is required in a much smaller number of cases chiefly because the disease

occurs less often but also because some cases respond favorably to x-ray treatment or to heliotherapy. Tuberculosis of the mesenteric lymph glands occasionally necessitates surgical removal particularly when the glands become encased and incapacitate the patient because of continued severe abdominal pain. Pulmonary tuberculosis has however come within the scope of surgery because of the successful work of Sauerbruch in Germany and a number of other surgeons in Europe and America. A plastic operation is performed on the chest which permits the diseased lung to collapse and enjoy more or less complete physiologic rest. Thoracoplasty can be performed when only one lung is involved in carefully selected types of cases.⁶ (See section on Surgery of Pulmonary Tuberculosis.)

Tuberculosis of the intestinal tract is generally limited to the lower ileum and cecum but other portions of the tract may be involved. These cases occasionally require excision or short circuiting but many of the patients respond to a prolonged hygienic regimen including rest and heliotherapy.

Tuberculosis of the peritoneum frequently becomes a surgical problem usually because of the difficulty of making a differential diagnosis. Often it cannot be distinguished from other diseases accompanied by a cecus particularly cancer unless an exploratory operation is performed. If the focus is abdominal and can be removed without great risk such a procedure is justifiable. Tuberculosis of the genitourinary tract is usually secondary to foci elsewhere.⁷ Frequently however the primary focus is small or quiescent and it may be wise or urgently necessary to remove the secondary focus. This is often a relatively safe and successful procedure in tuberculosis of the kidney but it is more difficult in tuberculosis of the epididymis or of the bladder.

Tuberculosis of bones and joints is still fairly common in children. It is of course hematogenous in origin and must therefore have a primary focus elsewhere. Surgical fixation of such lesions is frequently indicated.

(B) *Bacillus anthracis*—(See section on Anthrax.)

(C) *Bacillus diphtheriae* is of interest to the surgeon only because at times it may

be found as a contaminating organism in wounds and chronic ulcers which fail to heal Grossmann examined four hundred open wounds and found the true diphtheria bacillus in 5 per cent of them Some of the wounds healed promptly after the administration of diphtheria antitoxin

(D) *Diphtheroid bacilli* constitute a heterogeneous group of gram positive organisms They are pleomorphic often becoming coccoid or assuming bacillary forms which vary considerably in size and shape They are frequently found in the air and occasionally on the skin and in swollen lymph glands They are common inhabitants of the intestinal tract and are found in peritoneal exudates when there has been intestinal perforation Occasionally these organisms seem to be able to produce a trivial infection in clean operative wounds and may grow out in pure culture when the other contaminating organisms fail to do so

(E) *Bacillus subtilis* is of the same significance to surgeons as the diphtheroid bacilli except that it is not often found in peritoneal exudates It is a spore forming organism of low pathogenicity which may be used satisfactorily as a test organism in determining the efficiency of any sterilization process

(II) **Gram Negative Bacilli**—Gram negative bacilli have become increasingly important in recent years since penicillin has been available for clinical use Many of the gram negative organisms produce a substance which renders the penicillin inactive and when present in a mixture of bacteria in burns or accidental wounds may interfere with the therapeutic effect of penicillin

(A) *Bacterium coli* represents one of the most widespread groups of bacteria These bacilli are found almost universally in the intestinal tracts of man and animals appearing in the stools shortly after birth and remaining there throughout life Although they live within the intestinal tract they apparently do no harm to the host However when they are introduced into other tissues and organs they may cause profound illness and death With the constant trauma to the mucous membrane of the intestines from indigestible food particularly in the appendix and in the lower sigmoid and rec-

tum where the feces are inspissated the door is open for the entrance of these organisms into the deeper tissues Thus *B coli* may be carried to the neighboring lymph glands or to the liver From the liver it may be carried to the gallbladder by way of the bile or it may reach the gallbladder by passing up the cholecystus Being discharged in large numbers with the stool it naturally contaminates the area around the anus and frequently may be introduced into the vagina and urethra of females especially infants Owing to the difficulty of sterilizing these parts it is almost invariably introduced into the bladder during catheterization and it is the commonest organism found in either the spontaneous or post operative cases of cystitis and pyelitis

Bacterium coli is of interest to the surgeon chiefly because of its association with appendicitis and cholecystitis It may not be the primary cause of appendicitis but when the organ becomes inflamed *B coli* may pass through the grossly intact wall produce peritonitis and be recovered from the exudate in pure culture⁸ The other intestinal organisms seldom do this but if perforation takes place some representatives of all of the bacterial species present in the intestinal tract are discharged into the peritoneal cavity and may play a part in the subsequent infection⁹ In like manner when the intestinal wall is perforated by an ulcer or by a foreign body *B coli* plays a major role in any subsequent infection If the organisms then spread via the portal venous radicles to the liver multiple abscesses may form *B coli* reaches the gallbladder either from the liver via the bile or by passing up the duct It may precede or follow the development of stones but it usually shares with *B typhosus* and the non hemolytic streptococcus the infective role in the development of cholecystitis¹⁰

(B) *Bacillus typhosus* is of interest to the surgeon chiefly because of its relationship to certain complications of typhoid fever The chief of these are perforations of the intestine and cholecystitis Occasionally subperiosteal abscesses appear in the long bones and more rarely abscesses develop in the subcutaneous tissue elsewhere

Ulcerations of the intestines leading to perforations are almost certainly due to the inflammatory process

in Peyer's patches of the lower ileum. When perforation takes place not only the typhoid bacillus but all of the intestinal organisms are introduced into the peritoneal cavity. In such cases only prompt operation and closure of the perforation will prevent death. Frequently during the course of typhoid fever the patient complains of symptoms in the region of the gallbladder but in many cases there are no subjective signs until years after and then the mechanical factor of gallstones calls attention to the fact that a pathologic condition is present. In such cases the typhoid bacilli may be found in the stool but they usually disappear after removal of the gallbladder. In a few cases the organism establishes itself permanently in the liver or in the intestinal tract and the patient remains a carrier and a menace to society for life. Potentially bacteriophage a part of the body of such an infectio-

crated with chronic infections in the neighborhood of the alimentary canal especially gangrenous processes. Some investigators have insisted that it is the cause of such infections but it is usually merely a secondary invader and of little concern to the surgeon. A few authentic cases have been reported however in which it seemed to be pathogenic. In one case it apparently produced a thrombophlebitis of the jugular vein in the peritoneal region. The clot propagated itself back to the brain an abscess formed and the process spread with the blood stream as well producing an abscess of the lung.¹

(C) *Bacillus mucosus capsulatus* was originally thought to be the chief cause of lobar pneumonia but its occurrence in such cases is relatively rare. Its chief interest to the surgeon is due to the fact that it causes serious complications in certain diseases of the respiratory and alimentary tracts. Empyema or abscess of the lung in which this organism is found is almost invariably serious. This organism is rarely found alone in peritoneal exudates but when perforation has occurred and the organism has established itself with others in the peritoneal cavity it stubbornly resists all efforts to eradicate it. Not infrequently it is carried off to the liver and there it produces one or more abscesses which are almost always fatal.

(D) *Bacillus pyocyaneus* is ordinarily considered to be non pathogenic but it frequently is most annoying as a secondary contaminant in chronic infections especially those associated with the alimentary canal in which it is commonly found. The characteristic appearance and odor of the green pus indicate its presence and demand special measures to insure its removal. It is often extremely resistant to eradication and occasionally invades the deeper tissues. It has frequently been found in the blood stream. In such cases it rarely if ever produces metastatic foci and generally disappears from the blood when vigorous efforts are made to remove it from the portal of entry. When it occurs in a postoperative infection in a previously clean wound a serious complication usually results (Table 1).

(E) *Bacillus proteus* is frequently asso-

(F) *Hemophilus influenzae*—The role of this organism in infectious diseases particularly of the respiratory tract is still a moot question but a few authentic cases make it necessary for the surgeon to remember that the organism may at times produce suppurative pleurisy which requires surgical attention.

(G) *Bacillus mallei*—With disappearance of the horse from every day contact with man the surgical significance of *B. mallei* has steadily declined. The surgeon must remember however that this organism can produce serious lesions of the skin and of the subcutaneous tissues resembling the lesions of staphylococci or of anthrax which may be either extremely chronic or exceedingly acute and fatal.

II ANAEROBIC BACTERIA

Pasteur made the observation in his early bacteriologic studies that certain organisms grow only in a medium from which the air has been excluded.¹ Such organisms were called anaerobic bacteria and it was assumed that oxygen was deleterious to their existence.

A ANAEROBIC COCCI

The only strictly anaerobic cocci of interest to surgeons are gram positive non hemolytic streptococci which are occasionally found in putrefactive processes in the intestinal tract occasionally in foul infections around the teeth and tonsils and in foul lung abscesses. These organisms are not infrequently the cause of puerperal fever and may produce fatal septicemia. They are occasionally found in liver abscesses and in

chronic brain abscesses. They are generally of low virulence and may not be capable of producing disease except in symbiosis with other organisms or when there has been a necrosis of tissue from trauma or from the absence of blood supply.

They fall into two main groups—those which produce a foul odor and gas in artificial media and those which do not. Prevot has attempted a classification of these organisms, but the whole group needs further careful study.

D. ANAEROBIC BACILLI

Under this classification there are five species which are of importance to the surgeon. Four of them make up the gas gangrene group, and the other is the tetanus bacillus. Each of these organisms produces a powerful exotoxin which may be specifically neutralized by the appropriate antiserum.

(I) **Gram-Positive Bacilli.**—Practically all of the important gram-positive anaerobic bacilli are spore-forming organisms and, because of this characteristic, have been given the generic term of "*Clostridia*" by the nomenclature committee of the Society of American Bacteriologists.¹³

(A) *Clostridium welchii*.—By far the commonest and most important is the *Bacillus aerogenes capsulatus* of Welch and Nuttall,¹⁴ now called *Clostridium welchii*. It is the common cause of the gas gangrene which reached such enormous proportions in World War I. This organism is almost universally present in the intestinal tract of man and of most animals, just as is *Bact. coli*, but because it forms spores, it survives longer outside of the body and remains for a long time in fertilized soil. The filth of trench life and the frequency of contamination of gunshot wounds with soil and woolen clothing make it readily understandable why gas gangrene was so common among the wounded in World War I. In gunshot wounds this organism was frequently found when there was no evidence of its activity, and it must be considered to be essentially a saprophytic organism which becomes pathogenic only under certain conditions, namely, when it has been introduced in large numbers, when foreign bodies are present or when there has been

considerable destruction of tissue, particularly muscle, which offers it a favorable environment for growth and toxin production.

In civilian life, compound fractures are the precursors of a large proportion of the cases of gas gangrene because of the usually extensive injury to muscles and the contamination of the depths of the wound with street dirt.

Clostridium welchii is also of some importance in peritonitis. It rarely passes out through an intact intestinal wall, but if there has been a perforation which has per-

Fig. 8—Muscle fibers destroyed by the action of gas gangrene organisms. Note the paucity of leukocytes.

mitted the escape of intestinal contents, it is able to maintain itself in the peritoneum, although its significance there is not so great as when it is actively growing in muscle tissue.⁶ An infection with this organism is characterized by profound intoxication—high fever, rapid pulse, prostration and apprehension. Locally there is pain in the wound, redness, swelling, bronzing of the skin and crepitation, which is due to the generation of gas by the action of the organism on muscle tissue. The extent of the bubbles of gas in the tissues may be accurately determined by taking a roentgenogram of the affected part. When the infec-

tion has become established it travels with great rapidity up the muscle bellies and unless surgical extirpation is promptly applied with or without the aid of serum therapy the patient will almost certainly die.

(B) *Clostridium novyi*¹⁵ (C) *Clostridium septicum*¹⁶ and (D) *Clostridium sordellii*¹⁵ may be listed together as the other gas gangrene organisms. They can be readily distinguished from *C. welchii* by their cultural characteristics and by their neutralization with specific antitoxin. They all produce gas gangrene and are frequently present with *C. welchii* in severe war wounds. When these organisms are present alone the lesions which they produce are edematous rather than gaseous. Crepitation usually cannot be felt unless *C. welchii* also is present. Its presence must always be suspected in wounds contaminated by soil or fecal discharges or when edema or crepitation is present. Infections with gas gangrene organisms are so alarming in the rapidity of their spread and their high mortality that often treatment must be given before the causative organisms can be isolated and classified. The surgical treatment of the various types of gas gangrene is the same and now polyvalent sera are available for use until the causative organism can be identified. Then the specific antiserum should be used. After adequate surgical measures have been used to remove all involved tissues in cases of gas gangrene the wound should be treated daily with a creamy suspension of effective* zinc peroxide powder suspended in distilled water, care being taken to effect contact with every part of the wound. Although all of the gas gangrene organisms are essentially toxin formers producing true exotoxins which are rapidly disseminated throughout the body they are invasive also and spread extensively in the tissues. But strangely enough only as death approaches or after death is it possible to cultivate these organisms from the blood.

(E) *Clostridium tetani* is also a spore forming gram positive anaerobe but it is less widely distributed throughout nature than the gas gangrene organisms. It is less

often found in the human intestinal tract than *C. welchii* but is fairly common among persons who live in close contact with horses or cattle.¹⁷ Fertilized soil is the commonest source and the organisms must be anticipated in wounds contaminated with soil. As is the case with the gas gangrene organisms *C. tetani* is almost always accompanied by other organisms and the associated organisms generally play a part in the establishment of the tetanus bacillus. Unlike the gas gangrene organisms *C. tetani* does not invade the body; it remains at the site of entrance and produces its toxin which has a selective affinity for nerve tissue and possibly for muscle also. It has been generally accepted for years that the toxin passes up the motor nerves to the cord¹⁸ but Abel and his associates³ have cast some doubt on this theory. They believe that it attacks muscle directly and passes through the lymphatics to the blood stream and thence to the central nervous system involving especially the motor cells of the cord. The surgical treatment of tetanus is largely prophylactic. The debridement of the wound, the removal of foreign bodies and the scrupulous cleansing of the wound along with the administration of antitoxin are essential. If tetanus has made its appearance complete extirpation of the focus is of utmost importance in order to stop the manufacture of the poison and give the antitoxin the best possible chance to neutralize the toxin already liberated. Tetanus antitoxin is generally indicated as a prophylactic measure in all puncture wounds. (See section on Tetanus.)

(II) Gram Negative Bacilli.—There are a number of anaerobic gram negative bacilli which do not form spores but which are definitely pathogenic. They belong to the bacteroides and neorophorus groups. They are of some importance in symbiosis with other organisms in peritonitis and in chronic ulcerations and are associated with if not the cause of certain forms of chronic ulcerative colitis. The whole group requires further study.

III MICROAEROPHILIC ORGANISMS

The microaerophilic bacteria form a little known group of organisms which are intermediate between the anaerobes and aerobes. They grow best in an environment

* At the present time effective zinc peroxide is manufactured only by the Du Pont Chemical Co. and Inbuted by Merck and by Mallinckrodt.

with a diminished oxygen tension at least when they are first isolated from the human body. They may perhaps be aerobic organisms which have become modified by living for a time in the intestinal tract or in lymph glands. Such organisms are frequently missed with ordinary methods of cultivation or may grow sparsely aerobically. Two types of chronic infections have only fairly recently been recognized as being due to these organisms.¹¹

A Streptococci—Hemolytic microaerophilic streptococci have been found in pure culture in certain chronic ulcerative non-gangrenous lesions which generally occur on the abdominal wall but which may develop on any part of the body surface. They are characterized by an extensive ulceration with undermining of the skin and the development of sinuses which burrow down between the muscles into the pelvis or groin or into the vulva or scrotum. These infections have in the past existed for months or even years with gradual progression until death ensued as a result either of the erosion of blood vessels or of amyloid changes in the liver, spleen or kidneys. Recently however it has been found that in these cases there is a favorable response to local treatment with zinc peroxide and the outlook in such cases in the future is decidedly favorable.¹² (See section on Chronic Undermining Ulcer.)

Non Hemolytic Microaerophilic Streptococci—Similar organisms which are not hemolytic but which tend to produce met-hemoglobin on blood agar plates have been found in very chronic gangrenous lesions of the abdominal or chest wall following the drainage of peritoneal or pleural abscesses. The lesion is extremely painful and spreads slowly with a zone of adherent gangrenous slough without extensive undermining and burrowing or the formation of sinuses such as occur in the condition described above. Outside of the zone of gangrene there is a raised purple necrobiotic zone and beyond this is a red hyperemic zone in which the organism can be found in pure culture. In the gangrenous zone it is always associated with a staphylococcus. This disease seems to be a synergistic infection in which the streptococcus which alone is apparently non-pathogenic in some way paves the way for

the gangrenous action by the staphylococcus.^{21a} (See section on Chronic Gangrene.)

IV SPIROCHETES

The *Treponema pallidum* of syphilis can hardly be said to cause surgical infections although syphilitic lesions are frequently operated on when there has been a mistake in diagnosis. On the other hand some of the spirochetes such as *T. macrodentum* and *T. microdentum* and spirilla of the mouth frequently find their way into dental abscesses which may spread to the cervical lymph glands or to the lungs and produce foul smelling abscesses. They frequently occur also in foul infections of other parts of the body especially of the hands following human bites. Such cases are helped by the intravenous administration of neosalvarsan but frequently surgical drainage or amputation is also required. Zinc peroxide is usually effective in eradicating these organisms in foul smelling dental infections and human bites.

V HIGHLY MICRO ORGANISMS

A ACTINOMYCETES—(See section on Actinomycosis.)

B BLASTOMYCETES—(See section on Blastomycosis.)

C COCCIDIOIDES—(See section on Coccidioidal Granuloma.)

D SPOROTRICHIA—(See section on Sporotrichosis.)

POSTOPERATIVE SURGICAL INFECTIONS

In the second part of this section the factors have been discussed which favor or minimize contamination of an operative wound. There are also certain disturbances of the normal physiology which occur during or after an operation which favor the establishment of infection in other parts of the body. These affect chiefly the respiratory alimentary or urinary tract.

A Respiratory Postoperative Infections—During almost all general anesthetics and to a less extent with the action of sedatives or narcotics preliminary to local or spinal anesthesia there is diminution or suppression of the cough reflex. Frequently a particle of mucus or food or a drop of water enters the larynx and trachea in a normal

person who has not received any medication. It almost invariably starts a violent coughing attack which quickly dislodges the particle and frees the trachea from the offending substance. On the other hand it has been found that non-irritating substances such as oils may run down into the larynx without starting the coughing reflex. Certain inhalation anesthetics cause increased ventilation and increased depth and force of respiration favoring the entrance of mucus into the trachea and bronchi.¹⁵ With almost any anesthetic it may be assumed therefore that organisms and mucus from the mouth and sometimes blood become lodged in the respiratory tract below the glottis—the position being determined by the depth of the anesthesia, the size of the particle and the other factors previously mentioned. Furthermore sedatives, narcotics and anesthetics as well as pain limit the excursion of respiration and lessen the aeration of the lungs. Small bronchi or bronchioles particularly in the bases of the lungs then become shut off and the air in the alveoli which they supply becomes absorbed. Atelectasis results and if organisms are present the opportunity is given for them to multiply and produce their poisons. If they are sufficiently virulent to resist the phagocytic action of the lining cells they may destroy the cells and invade the tissues producing bronchitis, lobular or lobar pneumonia or occasionally pulmonary abscess. The pneumococci which are frequently present in the mouth are the organisms most likely to produce these infections, especially the pneumonias, but the other organisms also may play a role in the bronchitides and lung abscesses. The latter conditions frequently reveal the presence of anaerobic or microaerophilic streptococci or the oral spirochetes and fusiform bacilli. Sometimes bacteria are conveyed to the lungs in pulmonary emboli from infected foci. Even if sterile an embolus may produce an abnormal area in the lung which favors the establishment of organisms introduced from above. If the embolus is germ laden infection almost inevitably develops.

Efforts should be directed to minimize the occurrence of these infections. In certain operations the anesthetist may maintain the anesthesia at a level which does not completely

obliterate the cough reflex. Use of CO₂ and O₂ inhalation after operation has been advocated to increase the amplitude of respiration and to free the bronchi from accumulated mucus. Binders which limit the movement of the lower ribs should be avoided and every effort should be made to restore the normal physiology as soon as possible. Attempts have been made to minimize the bacterial content of the mouth and throat before operation by the use of various antiseptics but so far none has proved efficacious. Further efforts should definitely and constantly be made in this direction until something has been found which will readily diminish the number of postoperative respiratory infections. When they occur they readily respond in most instances to appropriate doses of sulfadiazine or sulfathiazole.

B. Alimentary Postoperative Infections

—Occasionally postoperative tonsillitis develops following inhalation anesthesia but only rarely after rectal or local anesthesia. Almost always the organisms which are active in these cases were present in the patient's throat before operation but occasionally they are introduced if a tube or metal airway is used. These objects may traumatize the tonsils and the churning of the pharyngeal mucus may favor the invasion of the organisms. Postoperative parotitis is a distressing complication of frequent occurrence in debilitated persons. It seems to be favored by dryness of the mouth. The offending organism is almost always the hemolytic *Staphylococcus aureus*. The organism probably reaches the gland by way of the duct although it is surprising that other organisms more common in the mouth do not occasionally cause parotitis. One can only surmise that the parotid gland is particularly susceptible to the staphylococcus. The esophagus, stomach and duodenum are not often affected by bacterial invasion after operation. Paralytic or mechanical ileus however may have a bacterial element. The stasis of intestinal contents inevitably causes retention of irritating substances both chemical and bacterial in contact with the mucous membrane which is stretched by the accumulation of gas and compromised by a diminished blood supply. The amount of absorption from intestinal

distention has been a matter for debate and experimentation. The facts are little known but the possibility of a large bacterial factor in the production of clinical symptoms can not be denied. The frequency of rectal irritation from the mechanical apparatus used to overcome postoperative distention occasionally favors invasion of the perirectal tissues by intestinal bacteria with subsequent abscess formation. This possibility should always be borne in mind and rectal treatments should not be continued longer or carried out oftener than is absolutely necessary.

C Urinary Postoperative Complications—Frequently after an operation in the lower abdomen or on the pelvic floor or perineum the reflex spasm of the sphincter of the bladder prevents evacuation and results in retention of urine and distention of the bladder. This may become so painful that it must be relieved by catheterization. It is difficult if not impossible to sterilize the meatus of the urethra and consequently any instrument is certain to carry organisms into the upper urethra or the bladder. If distention occurs again or if the bladder fails to empty completely the organisms may be retained, they may grow in the urine and invade the bladder wall. They may invade the ureters also either by entering the meatus and infecting the urinary column or by passing up in the wall. Thus pyelitis or pyelonephritis may develop. Infection occurs in a large percentage of patients who require catheterization. The organisms most often found are the *Bact. coli* and intestinal green streptococci both of which apparently grow readily in urine. Obviously catheterization is to be avoided if possible and always performed with the utmost care in order to minimize the introduction of organisms. It is also important to prevent the collection of residual urine and to remove speedily the contaminating organisms before they can gain a foothold. When they are once established it is difficult to eradicate them but this may be done by assiduously flushing the bladder with all time diuretics alternating with acidifying antiseptics or if that fails by the use of an appropriate and potent bacteriophage. Recent sulfathiazole has been found to be effective against certain strains but it is ineffective against others. When given by mouth it is elim-

inated through the kidneys if they are not diseased in sufficient concentration to inhibit the growth of the organisms materially.

HOW DO BACTERIA ENTER THE BODY?

The human body is covered by a layer of hornified epithelium of varying thickness which is punctured by the ducts of the sweat and sebaceous glands and by the hair follicles. At the orifices of the body the skin joins with mucous membrane which lines the inner surfaces of the alimentary, respiratory and genitourinary tracts and the conjunctival surface of the eyes. On the surface of the mucous membrane the ducts of various glands pour out secretions: saliva, mucus, bile, gastric and pancreatic juice, urine and various minor glandular secretions of the respiratory and alimentary tracts. Bacteria cannot penetrate the horny layer of the skin but certain species such as the staphylococci are able to live in the ducts and may at times grow there and produce poisons. Such toxic products may then have the power to destroy the thin layer of epithelium lining the duct and permit the organisms to enter the subepithelial layers. Organisms which cannot grow metabolize and produce lytic substances on or in the skin must await some mechanical force to transplant them into the deeper layers. On the surface of the mucous membranes particularly of the alimentary tract are substances which can be utilized by a large number of bacterial species for food which will permit them to grow and metabolize and give off poisons or waste products which may injure the surface epithelium. At the same time the inner surfaces of the body are subject to minor injuries which carry the surface organisms into the deeper tissues. It may be said in general that bacteria usually enter into the subcutaneous tissues through breaks in the continuity of the skin rather than through an erosion of the surface by bacterial products and bacteria enter the submucous tissues through the erosion of the surface by bacterial products rather than through wounds. Furthermore there are certain physiologic changes in the surface of mucous membranes which may render them liable to the invasion of bacteria. For example the congestion that occurs in the nasal mucous membrane in response to me-

chemical, chemical or thermal stimuli renders it more permeable than when it is not congested. Similarly in the genital tract the lining of the uterus after menstruation or parturition is more liable to penetration by organisms than it is normally. The congestion of the mucous membrane of the urethra during intercourse probably renders it more permeable to gonococci than it would be normally. In the alimentary tract there is always a certain amount of indigestible material which may traumatize or puncture the mucous membrane and permit organisms to enter. It is generally believed however that typhoid, cholera and dysentery organisms as well as the tubercle bacillus may pass through an intact intestinal wall. Any obstruction to the onward flow of the intestinal contents increases the possibilities of mechanical and chemical injury because of the greater time of contact of the irritating substance and because of the pressure exerted on the intestinal wall by the accumulated fecal fluid and gases. This may result in the cutting off of the blood supply so that the surface cells may die, disintegrate or be torn apart.

How Deep Must a Wound of the Skin Be to Permit the Entrance of Organisms?

—The basal layers of the epidermis consist of round or polygonal cells which have normal nuclei and are connected to neighboring cells by cellular bridges. No blood vessels enter the epidermis but there is a circulation of lymph beneath the bridges which nourishes the cells for the first few layers. Higher up the cells become smaller and flatter they begin to lose their nuclei and they become packed closely together. Still higher they lose their nuclei and become completely keratinized. Any cut or abrasion which penetrates to the layer around which fluid is circulating may carry organisms into these intercellular spaces. They may then be carried off in the current directly or may lodge in these spaces, colonize and produce poisons which erode capillaries or lymphatics and pave the way for deeper penetration by the organisms.

HOW DO BACTERIA SPREAD WITHIN THE BODY?

When bacteria pass the first barrier either because they have produced an erosion or

because they have been carried in through a wound they reach the subepithelial tissues. If purulent discharges have been introduced directly from another human source the dose of organisms may be large and accompanied by toxic products which may injure the tissue cells at once. Usually however the dose is small and the organisms have come from an entirely different environment. If they are to produce an infection the organisms must maintain themselves in the face of hostile forces, namely the tissue fluids, the blood and the phagocytic cells. As a rule the bacteria are promptly destroyed but if a few survive they will presently begin to multiply. To make a colony of organisms is produced and the waste or toxic products accumulate. If these products are fluid they may diffuse outward in all directions. The fluid may attract or repel leukocytes and according to its concentration may be destructive to the neighboring tissues and cause liquefaction, thus producing a little fluid space around the colony. Organisms may then be carried away from the surface of the colony by the currents of fluid circulating about the colony. These organisms will be stopped for a while however by some intercellular fibrils or by the endothelial lining of capillaries or lymphatics. As the lymphatic system is closed they cannot enter the lymphatics directly. They may however be picked up by the wandering cells of the blood or by the endothelial phagocytes and may be destroyed or carried into the capillaries or lymphatics. If phagocytosis does not take place the organisms may multiply and produce a new colony at a distance from the parent colony. The whole process perhaps being repeated there. The bacterial products besides liquefying tissue frequently cause thrombosis of capillaries and then there may be subsequent invasion of the clot by the liquefaction of the lymphatic or capillary wall. As the clot increases in size within the vessel the bacterial invasion follows until the next larger vessel is reached. Then this nidus may become thrombosed or pieces of the infected clot may be thrown off into the lymph or blood stream and carried to the next narrow portion of the capillary bed either in the lungs or the liver. If there are individual organisms or bits of blood clot

which are smaller than the capillaries, they may pass through the lungs to the pulmonary veins and then, coursing through the heart, may be thrown off into the arterial side and caught in the peripheral capillary network or destroyed in the blood. If caught, they may again start a metastatic colony with a repetition of this process until death ensues. For further details regarding these interesting processes of infection the reader is referred to Zinsser's book²² and to the author's chapter in Nelson's *Ioose Leaf Surgery*.¹¹

CHEMOTHERAPY IN SURGICAL INFECTIONS*

INTRODUCTION

Until 1935 the term chemotherapy was largely limited to the topical use of antiseptic agents in wounds. It has been only since then that chemotherapeutic agents effective in the sense that Paul Ehrlich first used the term have become available. Ehrlich coined this term to signify the destruction of special disease-producing living agents within the body of the diseased being, but in practical usage the term has been limited to the employment of agents which may be administered systemically, which will retain their activity against bacteria in the body and which will be transported by the circulation to the site of the infection and there provide a direct attack on the bacterial parasites. It is probably desirable to continue to apply the term antiseptic to agents which may be used only in sterilization of skin or in topical antiseptic therapy of open infected wounds.

In attempting to discover drugs which would aid the animal host to combat infection Ehrlich faced a problem of great complexity but he approached it with decided ingenuity. In the treatment of infections he was impressed by the possible usefulness of the aniline dyes which were originally introduced by his cousin Weigert for selective staining of bacteria in the tissues. Ehrlich reasoned that a dye which could selectively stain bacteria in the tissues might also produce a selective toxic effect on these bacteria. In pursuing this quest Ehrlich pushed aside the pessimistic attitude toward chemotherapy which prevailed at the opening of the 20th century. His distinguished contemporary von Behring had said: "It can

be regarded almost as a fact that the tissues of man and animals are many times more susceptible to the poisonous effects of disinfectants than are any of the bacteria known at present therefore before the antiseptic has a chance either to kill or to interrupt the growth of the bacteria in the blood or in the organs of the body the infected animal itself will be killed. The pessimism of him who declared that disinfection in the living body is for all times impossible appears to be only too justified. Actually Ehrlich never succeeded in developing a drug which could be used in the treatment of bacterial infections in man. He did show that trypan red was a drug effective in combating experimental trypanosomal infection of mice and subsequently he made his brilliant discovery of salvarsan which revolutionized the management of syphilis and very significantly prepared the ground for the discovery of sulfonamides by his fellow countryman Domagk in 1933.¹

Sulfonamides—It is of interest that the first sulfonamide drug, prontosil, was a red dye of the so-called azo type formed through the combination of *chrysoidin* with sulfanilamide. Sulfanilamide had been synthesized in 1909 but for more than twenty years it was employed only in the dye industry as a means of increasing the fastness of aniline dyes for wool protein. Apparently the German workers were not aware of the fact later brought to light by the French investigators, Monsieur and Madame Trepouel, that the effectiveness of prontosil was due to the sulfanilamide in the molecule and that the sulfanilamide split off from the dye as a result of the action of enzymes in the body fluids and then circulated in free and active form. This explained the interesting fact that prontosil itself was inactive in the test tube whereas sulfanilamide enjoyed a very considerable degree of activity against certain types of bacteria *in vitro*.

Considerations of space do not permit including in this chapter a detailed account of the historical development of the sulfonamide drugs. It is important however to call attention to the major contributions of Leonard Colebrook and his colleagues^{2,3} in defining the possibilities and limitations of sulfonamides in the treatment of one type of severe hemolytic streptococcus infection.

* The growing importance of chemotherapy in the prevention and treatment of surgical infections has led to the preparation of this special section on the subject. Obviously it would be impossible within such limits to present all of the subject matter on chemotherapy which should be understood by individuals engaging in the administration of these drugs. It is the purpose of this section simply to offer a broad view of the field and as far as possible to supply the rationale basis for selection and administration of the drugs in the principal types of surgical infections. The bibliography includes a number of publications to which the student is referred for supplementary reading.

namely puerperal sepsis. Colebrook was responsible for the following observations. First after treatment with prontosil or sulfanilamide the blood of the patient became rapidly endowed with the capacity of killing many times the number of hemolytic streptococci that would be killed by the blood of a normal subject or the blood of an infected patient prior to receiving the drug. This served to explain in a general way why the sulfonamides were effective as chemotherapeutic agents. Second he observed that the bacteria were not all destroyed in the body by the action of the drug and he correctly inferred that the major role of the sulfonamides was to interfere with the ability of hemolytic streptococci to multiply in the body but that the actual clearing of bacteria from the infected area occurred through the continued operation of the immunity mechanisms of the patient. He pointed out that sulfanilamide treatment was most effective in dealing with the true invasive factor in hemolytic streptococcal infections namely the multiplication of streptococci in blood and in tissues of fairly normal architecture. It was later observed by American workers⁴ that the use of sulfonamides in the body was limited in proportion to the amount of breakdown of tissue which occurred at the site of the infection and that necrosis and suppuration in the infected area resulted in liberation of substances which were specifically antagonistic to sulfanilamide both in the body and in the test tube as well. These fundamental principles developed by Colebrook and others have continued to apply to the field of sulfonamide therapy even in the face of the development of many new drugs enjoying a range of activity far greater than that of sulfanilamide itself. By 1942 both sulfathiazole and sulfadiazine had been discovered and had been found to be effective not only against most streptococcal infections but against pneumococcal meningococcal and gonococcal infections as well with the use of these drugs it appeared that mortality rates from peritonitis and from infection in accidental wounds would be significantly reduced and the attitude expressed by von Behring in 1904 had been replaced by a sense of confidence that still newer drugs would be found which would

have curative action in all types of bacterial infections.

The sulfonamides are limited in their usefulness in surgical infections in several important ways. In the first place most of the so called surgical infections are characterized at some stage in their development by the presence of a suppurating focus of infection in soft tissue or bone. If the sulfonamide is administered at a sufficiently early stage in the development of the infection namely before tissue breakdown has occurred through action of bacterial enzymes and interference with blood supply the further progress of the lesion may be checked however once breakdown of tissue has occurred the drugs are incapable of effecting the further destruction of bacteria in the focus and it becomes necessary to resort to surgical methods of eradicating the lesion. The next important limiting factor of sulfonamides in the treatment of surgical infections derives from the comparatively low degree of activity of sulfathiazole and sulfadiazine on the *Staphylococcus aureus*. The overwhelming majority of the infections which are called surgical are due to this particular organism including boils carbuncles acute and chronic osteomyelitis and most infections in operative and accidental wounds. Although the administration of these drugs has undoubtedly aided in effecting the localization of these infections and has probably reduced fatality rates as a result the fact remains that the usefulness of sulfonamides in these lesions falls far short of what could be hoped for the ideal chemotherapeutic agent, consequently, the development and use of penicillin is of great significance in the field of surgical infections.

Penicillin—Unlike the sulfonamides penicillin is not inhibited by the products of tissue breakdown and it is highly active against staphylococci when it can be brought into contact with them. Penicillin was actually discovered by Alexander Fleming⁵ in 1929 when he observed that accidental contamination of cultures of *Staphylococcus aureus* with the mold *Penicillium notatum* resulted in destruction of the staphylococci. He assigned the name penicillin to the secretion of this mold which contained the active antibacterial agent. Being impressed by the lack of toxicity of penicillin against

animals and against leukocytes *in vitro* he speculated on the possible usefulness of penicillin in the treatment of infections. The spirit of nihilism in respect to the possibilities of chemotherapy was so strong at that time that his work lay dormant for more than ten years—in fact until after the wave of enthusiasm for sulfonamide therapy had passed its peak. The demonstrable usefulness of the sulfonamides eventually dispelled this attitude of nihilism and with the war was added impetus. Fleming's work was finally followed up by a group of investigators at Oxford University in a series of studies commencing in 1940. These workers (Florey, Chain, Abraham and others^{7, 8}) succeeded in producing enough of the active agent to permit treatment of experimental infections in animals and they found that Fleming's intuition of a possible therapeutic usefulness for penicillin was actually capable of realization. After they had obtained encouraging therapeutic results in the treatment of staphylococcus infections in man it became a matter of great war time urgency to widen the scope of investigations on penicillin and to solve the problem of large-scale quantity production of this drug. Success in both avenues of work was rapidly achieved both in England and in the United States. By the spring of 1944 the scope of usefulness of penicillin in clinical infections had been extended well beyond the field of staphylococcal infections alone and the quantities of penicillin being produced were sufficient not only to meet the needs of the armed forces of Great Britain and the United States but also to permit extensive clinical investigations of infections in civil life as well.

Modern chemotherapy then has been developed around the utilization of these two types of agents, namely sulfonamides and penicillin. Both types of drugs possess the characteristics which are essential in the treatment of established infections in the body: both are of a sufficiently low order of toxicity to be of practical value in the treatment of infections in man and both possess the property of being active in the test tube and retain this activity against bacteria in surgical infections when they are present as constituents of the circulating blood and tissue fluids. In this respect the sulfonamides

and penicillin are radically different from most of the chemical agents which are toxic to bacteria, including the so-called antiseptics. In thinking of these drugs it is of the greatest importance at all times to keep in mind this fundamental distinction:

THE BASIS OF CHEMOTHERAPY

In the action of a chemotherapeutic agent in the body there are involved three main sets of variables. The bacteria act on the host; this is the infection. The drug acts on the bacteria by definition. The drug usually produces some effect on the host; this constitutes the third side of a triangle of chemotherapy. There are other additional actions which are included within the scope of this triangle. The host responds to the presence of bacteria through the operation

Fig. 9—The triangle of chemotherapy

BACTERIA → HOST

of the mechanisms of immunity. The host reacts to the drug and succeeds to a greater or lesser extent in inactivating or neutralizing the activity of the drug. Finally, the bacteria may also act on the drug and modify its chemical properties and its activity. This triangle of chemotherapy comprising a highly complex series of reactions is illustrated in Fig. 9. Some of these reactions will now be discussed in detail.

Bacteria produce deleterious effects on the host in three principal ways, each one of which is so closely related to the others that none may be considered as an entirely separate or distinct effect.

Invasion of the Host—First, bacteria which are truly pathogenic must possess the ability to multiply in the tissue fluids of the host, utilizing the available nutrient constituents of the host fluids in their metabolism and to a varying extent modifying

the host constituents to suit their own metabolic requirements. Some types of bacteria are more capable than others of carrying out such processes; for example, the clostridia through the activity of their metabolic products are able to maintain the reduced level of oxidation-reduction potential which they require in order to maintain their growth activity. However, in order to produce these metabolic products which are in effect toxins, it is essential that the organisms continue to multiply. When the hemolytic streptococcus produces a rapidly spreading infection in the body, as seen in erysipelas or cellulitis, the organisms multiply at a prodigious rate with an estimated generation time of less than thirty minutes. Through such geometric progression there occurs an enormous increase in the total number of infecting bacteria within a period of twenty-four or forty-eight hours. When the organisms multiply as rapidly as this time does not permit the development of suitable barriers against the active spread of the infection. Bacteria make their way into circulating fluids such as blood and lymph and are carried widely throughout the body producing bacteremia. The hemolytic streptococcus is undoubtedly the organism with the greatest predilection for producing bacteremia. *Staph aureus* multiplies at an equal rate but it tends to evoke a more complete local reaction at the site of the infection. An inflammatory barrier in the tissues around the site of infection is created rather early and the likelihood of widespread dissemination resulting from the infection is therefore not as great as is the case with the hemolytic streptococcus. It is in meeting the problem of invasive infection of these types that the sulfonamides and penicillin produce their most dramatic effects.

Toxemia in Infection.—Bacteria not only invade the tissues of the host but also tend to elaborate toxins which produce injury to the host in a variety of ways. As has already been mentioned, certain of these toxins are to be considered metabolic products of the organisms which are essential to them in maintaining proper conditions for their further multiplication and adaptation to the host. These toxins are of two main varieties:

Exotoxins.—First are the so-called exotoxins which are filterable non-protein products of bacterial growth of which the erythrogenic toxin of the hemolytic streptococcus is a good example. Diphtheria toxin and the toxin of *C. tetani* may also be cited. The exact mechanisms by which these toxins produce deleterious effects on the host are not at all understood; this aspect of infection constitutes a very important field of investigation which has as yet hardly been touched. The organisms produce these toxins only so long as they continue to multiply; once the toxin has been formed it may be neutralized by the presence in the host of the appropriate anti-toxin. Chemotherapeutic agents will not neutralize toxins of these types but by suppressing the ability of the organisms to multiply the further production of such toxins is indirectly reduced by the chemotherapeutic agents.

Endotoxins.—The other types of toxin are the so-called endotoxins. These substances are actually protein fractions composing part of the structure of the bacterial cell. As bacteria die out or are destroyed in the body, these cell fractions become liberated into the medium and are then absorbed into the systems of the host. Some of them are highly lethal in their effects but here again the exact nature of their poisoning actions is not at all understood. Among infections in the general field of surgery, a good example of such toxemia is peritonitis due to bacteria commonly found in the intestine. The colon bacillus is not a highly invasive organism in the sense that the streptococcus and staphylococcus are invasive. However, the colon bacillus shares with other members of the family of colon typhoid dysentery bacilli the presence in its structure of highly toxic protein fractions which play a major role in the pathogenesis of peritonitis. Neutralization of these endotoxins by antitoxins is far less readily carried out than is neutralization of exotoxins; here again, however, the ability of chemotherapeutic agents to suppress the growth activity of endotoxin-producing organisms within the body tends to limit the amount of toxins produced and thus results in marked benefit to the patient. There is some evidence that sulfonamides may play a part

in neutralizing the actions of certain endotoxins but this work needs further confirmation

Local Destruction of Tissue in Infection—Not only do bacteria invade the body and produce toxemia of the varieties described but their presence in the body tissues and the local reaction of those tissues to their presence tend to lead in varying degrees of damage to the architecture of the tissues. It is this element in bacterial infection which is of particular importance in most surgical infections for the characteristic which most clearly separates surgical infections from other types is the production of irreversible damage to the architecture of the tissues necessitating the replacement of normal tissue with scar tissue in the healing process. Surgical procedures must be used to aid in the removal of products of irreversible damage to the tissue and to facilitate completion of the healing of the wound which results. Destruction of tissue due to infection occurs by way of two mechanisms first through the locally destructive action of proteolytic enzymes which are formed by the organisms particularly by the staphylococcus and by certain of the clostridia and second by interference with the blood supply within the infected area. Some organisms produce toxins which act locally to cause thrombosis in capillaries and in blood vessels of even larger size. Operation of this mechanism may limit the dissemination of the infection but does so at the cost of local reduction in the blood supply and subsequent death of tissue in the infected area; moreover the edema which occurs at the site of infection produces local tension which may cause complete obliteration of afferent blood vessels and thereby lead to local anoxia and death of tissue. Chemotherapeutic agents must be administered in time to prevent the lesion from reaching the stage of impairing the blood supply in the infected part if they are to meet successfully this factor in infection. Once the blood supply has been cut off not only are conditions more favorable to the continuation of local bacterial growth but also the access of the drugs to the necrotic area will be limited to their ability to permeate dead tissue deprived of the capillaries through

which the drug normally gains access to the area of infection.

Chemotherapeutic agents must primarily suppress the ability of bacteria to multiply in the intact tissue and in the body fluids of the host in so doing the toxemia and the local destructions of tissue by the bacteria will be checked. Let us now turn to another side of the triangle and consider the actions of chemotherapeutic agents on bacteria in the body.

DRUG → BACTERIA

Paul Ehrlich hoped that there would be found an agent with the properties signified by the term *therapia sterilisans magna*. With such an agent it was hoped that the administration of a single large dose would bring about the selective mass destruction of bacteria within the body and would result in immediate recovery of the patient from the state of disease produced by their presence. Experience has shown however that the chemotherapeutic agents which are of value in treating infection produce their selective action on bacteria—while sparing the host—by acting in a subtle way upon some stage of a metabolic process upon the continued operation of which the bacteria depend for their survival. Thus the action of sulfonamides and penicillin is in no sense a destructive one such as that produced by carbolic acid or alcohol—agents which produce complete and irreversible damage to the structure of bacterial protoplasm. The true effect of the chemotherapeutic agent is to block completion of an enzyme reaction upon which the organism depends for its continued multiplication so that the organism ceases to proliferate when it comes into contact with an inhibitory concentration of the drug. This mechanism has come to be termed *bacteriostasis* in contradistinction to the *bactericidal* action of those antiseptics which actually destroy the bacteria on contact with them. It is the very subtlety of their action which probably permits the sulfonamides and penicillin to act on bacteria in the body. A chemical destruction of bacterial protoplasm in the body would undoubtedly be accompanied by destruction of host protein as well and the net usefulness of the agent would be lost thereby.

Sulfonamides—There is a good deal of evidence that the sulfonamides produce their effects on bacteria in the body because they bear a close chemical resemblance to *p*-aminobenzoic acid. The latter substance is presumably essential to bacteria and must either be produced by them or supplied to them in the medium. When a sufficient concentration of sulfonamide is present in the bacterial environment the molecules of sulfonamide enter the sphere of the chemical reactions of the cell where by masquerading as molecules of *p*-aminobenzoic acid without possessing the nutrient characteristics of this substance they wreck the continued operation of the particular enzyme system with which *p*-aminobenzoic acid is concerned. Of interest is the fact that the bacteriostatic action of the sulfonamides can be suppressed at any time by the addition of a high concentration of *p*-aminobenzoic acid to the medium. Sulfonamide can only block bacterial metabolism when the ratio *sulfonamide* : *p*-aminobenzoic acid is favorable to the sulfonamide. The foregoing concept of the mode of action of sulfonamides was first advanced by Woods,¹¹ and of several theories extant it is the one which appears to be most widely accepted by students of this subject. The concept of the competitive relationship between sulfonamides and *p*-aminobenzoic acid has contributed much to the development of an understanding of the nature of chemotherapeutic phenomena. Another point of considerable practical importance in connection with the mode of action of sulfonamides is the fact that peptone, a common constituent of laboratory culture media and similar products of the degradation of animal protein which are present in dead tissue have an effect like that of *p*-aminobenzoic acid in suppressing the bacteriostatic action of sulfonamides.¹ It was at one time thought that this effect of peptones and other proteolytic products was due to their content of *p*-aminobenzoic acid but a good deal of doubt now prevails that such an explanation is adequate. Whatever may be the true explanation of this tendency of sulfonamide action to be suppressed in the presence of dead tissue it is a phenomenon of great practical importance in chemotherapy with sulfonamides. It explains why sulfonamide

therapy may be highly effective in the invasive stages of an infection before proteolytic degradation of tissue has commenced and so limits the spread of infection in architecturally intact tissues and yet fails to influence the persistence of bacteria in abscesses and areas of gangrenous or suppurating tissue.

Penicillin—Comparatively little is known of the exact nature of the action of penicillin; presumably the action is one of even greater subtlety because the actual amount of penicillin necessary to induce bacteriostasis in the body fluids is less than 1/1000 as great as the concentration of sulfonamide required to produce an effect of similar magnitude.¹³ It is suggested that the locus of penicillin action in the bacterial cell must be a mechanism which is more delicately balanced in relation to bacteria than it is in relation to host cells because penicillin produces no interference with the metabolism of host cells even in concentrations several thousand times that required to suppress the growth of bacteria in contact with those cells. Penicillin is not inhibited by *p*-aminobenzoic acid and peptone but it is destroyed by acids, by contact with certain metallic ions, by heat and by the enzyme 'penicillinase'. Penicillinase is secreted by some of the organisms such as the colon bacillus which are resistant to penicillin. For this reason the action of penicillin against susceptible gram positive organisms may be impeded if gram negative bacilli are also present in the lesion.

HOST → BACTERIA

The third reaction of major importance in the triangle of chemotherapy is the action of the host on bacteria. Since chemotherapeutic agents simply suppress the ability of bacteria to multiply and do not actually destroy them it is apparent that the final disappearance of living organisms from the infected host must be the result of the action of mechanisms such as phagocytosis and bacteriolysis by leukocytes and humoral agents normally present in the host. The presence of the chemotherapeutic agents tends greatly to increase the efficiency of phagocytosis as a clearing mechanism. Under conditions of invasive infection when bacteria are multiplying with unre-

strained vigor in the host the ingestion of bacteria by leukocytes may simply lead to the destruction of the leukocytes by the bacteria rather than the reverse. By preventing continuous proliferation of bacteria within leukocytes the bacteriostatic drug makes effective a mechanism which without the drug would fail to meet the desired objective. The usefulness of sulfonamides and penicillin is therefore greater in types of infections and in anatomical locations which are characterized by the development of an active phagocytic response. For example sulfonamides appear to be of specific usefulness in the treatment of infections in cavities lined by serous membranes in which inflammation tends to produce a particularly striking degree of phagocytic activity. This probably accounts for the clinical usefulness of sulfonamides in treating mixed infections of the peritoneal cavity in spite of the comparatively low susceptibility of intestinal organisms to the bacteriostatic action of sulfonamides. In some infections sulfonamide action may provide 90 per cent of the background of recovery, while the operation of immunity mechanisms provides only 10 per cent. This is apparently the case in pneumococcal pneumonia. However in other types of infections such as the form of peritonitis just mentioned the relative importance of the two agents may be reversed. Thus the action of chemotherapeutic agents in the body must at all times be viewed as only one of the elements in the process of recovery from the infection. It is of great importance to provide as far as possible conditions in which phagocytosis and other mechanisms of immunity are at optimal effectiveness. If the surgeon keeps this point in mind he will not depend on sulfonamide drugs to destroy bacteria in dead spaces and in the interstices of a foreign body within which leukocytes cannot function efficiently. He will make every effort to avoid leaving dead spaces and foreign bodies within wounds. Furthermore when he considers the marked inhibitory effects of the products of tissue breakdown on sulfonamide action he will not depend on sulfonamides to prevent infection of wounds in which the tissues have been so crushed by the primary injury or by surgical procedures

as to bring about the liberation of products of tissue degradation into the wounds. In handling wounds he will direct his efforts toward minimizing the sources for the liberation of such sulfonamide-inhibiting products.¹⁴

HOST \rightleftharpoons DRUG

The next set of chemotherapeutic phenomena comprises the interreactions of the host and the drug. These reactions are of two main types: first those concerned with the way in which the host absorbs, transports and excretes the drug, and second the toxic reactions of the host to the drug. The first set of phenomena constitutes the *pharmacology* of the drug and the second the *toxicology*. (For a detailed discussion of these topics see Spink's¹⁵ monograph.) The pharmacology and toxicology of sulfonamides and penicillin will be briefly discussed in turn.

Pharmacology of Sulfonamides—It is a general characteristic of effective chemotherapeutic agents that they retain their essential chemical integrity after absorption into the body fluids. Obviously a drug which reacts rapidly with constituents of body fluids will probably in the process lose its ability to act upon bacteria. This constitutes an important reason for the generally unsatisfactory results of attempting to use chemically active antiseptics against bacteria in infected wounds.

The sulfonamides are absorbed fairly rapidly from the gastrointestinal tract. They tend with the same rapidity to be transported throughout the various tissues and organs of the body, and in general they become distributed with notable uniformity throughout the body water. Excretion through the kidneys commences promptly and proceeds at a rate which varies somewhat with different members of the sulfonamide series. Sulfathiazole is excreted with the greatest rapidity, sulfanilamide and sulfadiazine being removed at a somewhat less rapid rate. One of the possible avenues for improving the effectiveness of sulfonamides is through the development of compounds which while no more toxic are excreted less rapidly and therefore require smaller and less frequent doses. Sulfamerazine is a drug with chemotherapeutic properties quite sim-

lar to those of sulfadiazine but one which apparently enjoys the property of slow excretion.¹⁰ The sulfonamides appear in almost all of the body secretions including saliva, tears, sweat and wound exudates. The concentrations of various sulfonamides in the cerebrospinal fluid offer a rough index of the efficiency of their transport. Sulfathiazole appears in spinal fluid in a concentration only about 30 to 40 per cent of that existing in the circulating blood whereas the corresponding factor for sulfanilamide and sulfadiazine is in the range of 80 to 90 per cent. For this reason there is some theoretical advantage in using the latter drugs in the treatment of meningitis. The rate of absorption of these sulfonamides from wound depots tends to parallel their solubility.¹⁰ Since sulfanilamide is by far the most soluble member it tends to be most rapidly absorbed from wounds and from the peritoneal cavity. Sulfathiazole is absorbed with considerably less rapidity and sulfadiazine is so insoluble as to resist local absorption for many days. These considerations are of practical importance in the local use of the drugs in the prevention of infections in wounds and burns. It is desirable to balance the factor of drug concentration against the need for prolonged local action. Where local concentration is high as is the case with sulfanilamide the drug tends to be non persistent and may be all gone within forty eight hours. However when a less soluble drug such as sulfathiazole is used the concentration of the drug in the fluids bathing the wound may remain in the effective range for several days. On the other hand a drug which tends to persist within the wound for several days is likely to set up a local foreign body reaction which is undesirable and may contribute toward delay in wound repair.

The only significant chemical modification of the sulfonamides which occurs during their passage through the body is the acetylation of the drug which takes place in the liver. Once the drug becomes acetylated it loses its bacteriostatic activity. The proportion of the drug so neutralized differs with each member of the series but is not significantly high with any of the sulfonamides now in common use.

A pharmacologic consideration of major

importance is the tendency of some of these drugs particularly sulfathiazole and sulfadiazine to crystallize out in acid urine. The process of crystallization within the kidney parenchyma results in obstruction to the formation and excretion of urine and large calculi may be formed in the calices of the kidney. This tendency may be overcome by maintaining an adequate urinary output in excess of a liter a day and by the administration of sufficient alkali in the form of sodium bicarbonate to preserve the pH of the urine at neutrality or above. In practice it seems necessary to give approximately 20 Gm. of sodium bicarbonate every four hours in order to achieve this objective. [The intravenous administration of 1000 cc. of one sixth molar sodium lactate solution will usually alkalinize the urine for twenty four hours.—Ed.] This particular deleterious effect of the sulfonamides is discussed in relation to pharmacology because of its association with the matter of excretion of the drugs. In the case of sulfadiazine it represents the most important unfavorable effect of the drug. It is not an important consideration in relation to sulfanilamide because the solubility of this drug (and of its acetylated derivative) is so high that there is no tendency for the formation of crystals in the urine.

Toxicology of Sulfonamides—The most important toxic effects of the sulfonamides are a result of the development of sensitization to one or several members of the group. A factor of time is required for the development of sensitization and serious reactions of this type will rarely occur unless treatment is continued for more than ten days. The reactions take the form (in progressive order of severity) of skin rashes, drug fever, hemolytic anemia, agranulocytosis and exfoliative dermatitis. Fortunately the order of frequency of these reactions reverses their order of severity. The severe reactions are likely to occur only when drug treatment is continued following the development of one of the milder manifestations of hypersensitivity. Therefore if patients receiving sulfonamides are watched carefully for the development of skin rash, fever and progressive anemia the development of the severe and fatal complications may usually be forestalled. Once an individual has been

sensitized to one of the sulfonamides he may or may not be sensitive to another member of the series but the sensitization tends to be maintained for long periods of time therefore sulfonamide therapy must be administered with great caution to individuals who at some previous time have demonstrated any manifestations of hypersensitivity. It is a matter of considerable interest that individuals will rarely show these toxic reactions to sulfonamides until after manifestations of active infection have subsided. It is not known whether this is merely related to the duration of therapy or whether there is some basic immunological reason for the lack of association between sulfonamide sensitivity and active invasive infection by bacteria against which the patient has not yet acquired an immunity.

Pharmacology of Penicillin—Penicillin is utilized more efficiently when given parenterally than when taken by mouth. Like the sulfonamides when injected intramuscularly or intravenously it is rapidly transported throughout the circulating body fluids and lymph but unlike the sulfonamides it does not appear in significant concentrations in saliva, sweat, tears and spinal fluid. Penicillin does not appear to pass readily across endothelial or serous membranes a fact which is surprising in view of its relatively low molecular weight. It is excreted with great rapidity by the kidneys and in the bile so that a given dose administered intravenously may disappear entirely from the circulating fluids within two to three hours. It is therefore customary in severe infections to give penicillin by continuous intravenous drip or intramuscularly at intervals not exceeding three hours in length. If penicillin is administered by mouth approximately five times the parenteral dosage is required to maintain comparable blood levels and intervals of three hours should be employed. It is likely that new vehicles for oral penicillin which will make oral therapy more efficient will soon be available. However care must be taken to give the drug according to a rational plan designed to maintain an adequate blood level; sub-effective doses are likely to cause the infecting organisms to become penicillin resistant. The failure of penicillin to appear in significant concentrations in spinal fluid and in loculated exudates offers a theoretical basis for employing

intrathecal injections of the drug in the treatment of meningitis and intrapleural injections in treating empyema. Once topical injection of penicillin has been performed the resulting concentration within the cavity tends to be maintained for many hours and single daily instillations are usually sufficient. As would be expected from its solubility and rapid absorption penicillin rapidly disappears after local application to wound surfaces. If penicillin is to be of practical usefulness as a local application to wounds prior to their closure some means must be found to retain it within the wound for a much longer period than is possible when aqueous solutions or powdered forms are used.

Toxicology of Penicillin—A remarkable characteristic of penicillin is its virtual freedom from toxic action in the body. The occasional reactions of fever and urticaria which have been reported are probably due to impurities in the commercially available products and are not due to penicillin itself. The basis for this statement is the fact that the frequency of these reactions has tended to diminish as products of greater purity have become available.

SUMMARY

The theoretical basis for the use of chemotherapeutic agents in the treatment of infections and the general characteristics of the drugs now available for such use have been reviewed in some detail. The essential characteristics of an effective chemotherapeutic agent may be summarized as follows: 1 The drug should be active *in vitro* against pathogenic bacteria and should retain this activity within the body. 2 The drug should have a low tendency to react directly with host proteins so that it will not be inhibited or inactivated by normal constituents of the body. 3 It should be bacteriostatic rather than bactericidal that is it should exercise a subtle interference with a vulnerable phase of bacterial metabolism rather than a powerful destructive effect on the bacterial protoplasm. 4 It should be readily absorbed from the site of administration and should be rapidly transported throughout the body so that it will be able to reach the actual site of infection in an active concentration. 5 It should not exercise an inhibitory effect on phagocytosis. 6 Its toxic

actions on tissue cells through direct contact should be minimal

It is also possible to assign certain general characteristics to bacterial lesions most likely to be susceptible to the action of chemotherapeutic agents such as sulfonamides and penicillin as follows

1 The lesion should be due to a continuation of parasitic bacterial activity. A chemotherapeutic agent should not be expected to possess curative value in lesions where the bacteria are present simply as saprophytes and where active invasive infection no longer exists

2 The bacteria must of course be susceptible to the chemotherapeutic agent employed

3 The blood supply within the infected area should be adequate to permit transport of the drug to the site of bacterial activity in effective concentration. A lesion which is isolated from free circulation of blood and lymph will not be responsive to chemotherapeutic agents administered systemically but may yield to local therapy with the agent

4 There should not be present in the lesion a neutralizing concentration of any substance which inhibits the particular agent employed. In the case of sulfonamides the most important inhibiting substances are found in products of tissue breakdown and necrosis. In the case of penicillin the most important inhibitory substance is the enzyme penicillinase, a by-product of the growth of penicillin resistant bacteria such as the colon bacillus

5 There should exist conditions favorable to the effective operation of antibacterial mechanisms such as phagocytosis

In general infections will be most responsive to treatment administered early rather than late therefore it is incumbent on the surgeon to institute chemotherapeutic treatment as soon as an accurate diagnosis has been made. Specific treatment must be designed to meet the particular conditions which exist in each individual case. For this reason the discussion of chemotherapeutic management of the various types of infections will be presented in rather general terms. Sound application of chemotherapy cannot be made through a resort to rule of thumb but must be based upon a clear definition of the objective in each case and

upon a fundamental knowledge of the properties of the therapeutic agents which are available

PRACTICAL USE OF CHEMOTHERAPEUTIC AGENTS

Bacteriologic Basis for Selection of Drugs—Prior to the introduction of penicillin the sulfonamides represented the only chemotherapeutic agents of practical usefulness in the treatment of infections. Now however a state of transition exists in which the increasing supply of penicillin is making it possible gradually to substitute this drug for sulfonamides in those conditions in which it is definitely superior. Since the sulfonamides are likely for some time to remain cheaper and more readily available than penicillin it will probably be desirable for the present to continue the sulfonamides in those conditions in which the drugs are of approximately equal value. For this reason the sulfonamides should be used in the treatment of most acute hemolytic streptococcus infections and in pneumococcus pneumonia with penicillin being reserved for those cases in which the patient fails to respond to a reasonable period of sulfonamide therapy. Among the sulfonamides *sulfadiazine* is the drug of choice under most conditions because of its broad range of effectiveness and its comparatively low toxicity. Sulfonamides are preferable to penicillin in the prevention and treatment of peritonitis due to intestinal bacteria such as the colon bacillus which is in itself highly resistant to penicillin. The latter drug may be used in selected cases in which persistence of active infection is clearly due to the presence of *Staph aureus* or a hemolytic streptococcus and in which sulfonamide therapy has been shown to be ineffective. Penicillin is clearly the drug of choice in the treatment of all infections which are due to *Staph aureus* including cellulitis, bacteremia, pneumonia, empyema, arthritis, and meningitis. It is also apparently of greater value than sulfonamides in the treatment of infections due to *Clostridium welchii* and other members of the gas gangrene group. If penicillin is available it should be used in preference to sulfonamides in the prevention of invasive infections in severe accidental wounds compound

fractures and burns. The reason for this is that most of the severe infections likely to occur in such wounds are due to types of bacteria susceptible to penicillin chiefly staphylococci, streptococci and clostridia. It is therefore apparent that the sulfonamides are no longer of dominant importance in relation to surgical infections and that penicillin seems likely to enjoy far wider usefulness in surgical practice than the former drugs. (For a review of the current clinical experience with penicillin in surgical infections see the report by Lockwood, White and Murphy¹⁸) [For the use of penicillin in peritonitis see report of Faulex, Duggan, Stormont and Pfeiffer³¹—Ed.]

Treatment of Invasive Infections. Including Bacteremia.—Most acute surgical infections involve what might be called an invasive component. This may be manifested by the existence of positive blood cultures or may be manifested only by evidence of a process which is spreading progressively from its site of origin. For example a carbuncle on the back of the neck shows an invasive component during its early stages which consists in the area of spreading cellulitis peripheral to the central focus from which the lesion originates. The overwhelming majority of acute infections which display an invasive component are due to the hemolytic *Staph. aureus* and the hemolytic streptococcus. The problem of treatment of the invasive component is fundamentally the same regardless of the particular type of infection and the structures or organisms concerned. The objective should be to bring about as rapidly as possible suppression of active bacterial proliferation in the invaded tissue, blood stream or lymphatics. If the organism is a hemolytic streptococcus treatment with sulfadiazine using an initial dose of 2.0 to 4.0 Gm. followed by 1.0 to 1.5 Gm. every four hours will usually bring the invasive component under control. Sodium bicarbonate 2.0 Gm. every four hours should be given along with the sulfadiazine. If the organism is a staphylococcus or one of the anaerobes of the gas gangrene group penicillin is to be preferred when available. The dosage of penicillin should be approximately 150,000 to 200,000 units per day given either by continuous intravenous drip or by repeated in-

tramuscular injections every three hours. If penicillin is not available the above dose of sulfadiazine should be employed. In connection with the administration of the specific chemotherapeutic agents the management must include very careful clinical observation to detect any focus of localization at the earliest possible time. If the patient tends to show continuous improvement under treatment with the specific chemotherapeutic agent it is permissible in most cases to temporize with the treatment of the local focus. However if he fails to improve after two or three days of intensive therapy careful consideration should be given the question of surgical drainage or removal of the focus of infection. This course is particularly applicable in the treatment of suppurative meningitis secondary to middle-ear disease and of acute osteomyelitis with or without bacteremia. At one time it was necessary to stress employing surgical procedures on these patients at the earliest possible time but now that powerful chemotherapeutic agents are at hand it has become possible to await a time of election after the acute invasive infection has subsided before proceeding with surgical intervention. This tends to minimize the extent of surgical intervention and avoids the superimposition of tissue trauma at the particular period when much depends upon the unimpeded operation of immunity mechanisms at the site of inflammation.

Along with the administration of chemotherapeutic agents it is very important to administer blood and plasma for the treatment of anemia and shock, oxygen for correction of cyanosis and intravenous or oral fluids for maintenance of proper hydration. Since the patient with high fever tends rapidly to exhaust his reserves of protein it is necessary to administer a diet high in protein and carbohydrates resorting if necessary to parenteral administration of plasma and protein hydrolysates. The local treatment of the focus of dissemination should include complete immobilization (with application of splints if the focus is in an extremity) and elevation. Immobilization encourages the establishment of a protective inflammatory barrier at the periphery of the focus and elevation helps to maintain circulation of the inflamed part by reducing

edema. If the focus is in the face the patient should be kept in a semi erect position unless he is in shock and talking and chewing should be forbidden in order to minimize movements of facial muscles. In a majority of cases a thorough application of these measures will bring the invasive component of the infection under control the patient's temperature and pulse will come down and a sense of well being will replace the preexisting state of anxiety of both patient and physician. A subsidence in the signs of acute inflammation within the focus itself may also occur. The surgeon is then confronted with the problem of how to deal most effectively with the local focus. If treatment has been begun sufficiently early in the course of the disease to prevent the development of abscess formation at the local site it is likely that continuation of chemotherapy will result in the patient's complete recovery without surgical intervention. However in the majority of cases some degree of irreversible damage within soft tissue or bone will have occurred. The presence of an abscess may be reflected by clinical evidence of swelling and fluctuation by persistence of marked pitting edema in the skin overlying the inflamed region and by local pain and tenderness. Under such conditions the surgeon should not hesitate to carry out surgical drainage. The operative procedure should be adequate to permit removal of all of the pus and necrotic tissue which may have formed. Subsequent local treatment of the wound will depend upon the type and locality of the lesion this subject will be discussed in connection with local therapy of infected wounds. Each of the general types of infections to be discussed subsequently may involve at the outset the management of an invasive component as described above. However regardless of whether the infection is in a serous cavity in soft tissue or in bone the fundamental management will be along the lines outlined in the foregoing paragraphs.

Infections of Serous Cavities—Empyema.—Chemotherapeutic agents may be employed in prevention of empyema as well as in its treatment. The use of sulfonamide drugs in the treatment of pneumococcal pneumonia has greatly reduced the incidence of empyema as a complication of this dis-

ease. However empyema may occur in spite of sulfonamide therapy but the infection in the pleura is usually of a comparatively low grade character and is associated with the development of a very thick inflammatory capsule with varying amounts of fibrin in the exudate. Another serious form of empyema is that occurring after pneumonectomy and lobectomy. There is evidence that postoperative infections of the pleural cavity of this type may be prevented by the administration of penicillin to patients undergoing such operations. Administration of the drug should be commenced five to seven days before operation in dosage of 100,000 to 150,000 units per day and should be continued for seven to ten days after operation. This appears to be a particularly striking example of the use of a chemotherapeutic agent in the prevention of postoperative infection. The treatment of empyema has become somewhat modified through the availability of effective chemotherapeutic agents. It was formerly advisable to carry out closed drainage at the earliest possible time followed by open drainage with rib resection if the former procedure was ineffective. However empyema developing in a patient under treatment with chemotherapeutic agents is a less acute problem and it now seems desirable to employ repeated daily aspirations of exudate followed by injections of a chemotherapeutic agent into the cavity. Penicillin appears to be of greater usefulness than the sulfonamides in connection with such local use. Apparently the sulfonamides tend to be inhibited by the pus itself whereas penicillin is not, and the latter drug is effective against most of the pathogenic bacteria commonly found in empyema. When conservative treatment of this type fails to result in sterilization of the cavity and in progressive diminution in its size it will be necessary to employ open drainage, rib resection and possibly decortication of the lung namely excision of the inflammatory wall so that the lung can re-expand and fill the cavity. However it may be desirable to postpone this procedure for several weeks while awaiting improvement from conservative treatment.

Suppurative Arthritis.—The treatment of suppurative arthritis is essentially similar to that outlined for empyema. It is important

to maintain immobilization of the joint during the period of acute infection but active movement should be resumed as soon as possible after subsidence of the active process. Treatment should combine the use of systemic chemotherapy with aspiration and local introduction of penicillin as indicated. Here again the performance of radical drainage may be postponed and in the majority of cases may be avoided altogether.

Peritonitis—Chemotherapeutic agents may be employed in several ways in the prevention of peritonitis. In preventing peritonitis as a complication of operative procedures on the gastrointestinal tract the primary requirement of course is that the operation shall be technically satisfactory as regards maintenance of blood supply of the bowel at the site of anastomosis. No chemotherapeutic agent can succeed in preventing postoperative complications from massive necrosis of bowel or leakage at the suture line. Furthermore the surgeon must necessarily prevent the development of distention of the bowel proximal to the anastomosis by effecting adequate preoperative decompression. The role of chemotherapeutic agents is to prevent proliferation on the peritoneal surfaces of bacteria which have inevitably gained access to these surfaces during the course of the operation. Sulfonamides may be employed in three ways in prevention of peritonitis of this type. First the patient may be given preoperative doses over a period of six to seven days of a sulfonamide such as succinyl sulfathiazole which is retained within the gastrointestinal tract. This will bring about marked diminution in numbers or even complete disappearance from the feces of coliform bacteria and clostridia.¹⁹ The numbers of intestinal streptococci are not affected by this treatment. The dosage of succinyl sulfathiazole is 0.25 Gm. per kilogram of body weight per day divided into six doses administered at four hour intervals. This should be continued for five to seven days after operation. The purpose of sulfonamide therapy of this type is to minimize the number of pathogenic bacteria likely to gain access to the peritoneal surfaces during and following the operation. The second method of employing sulfonamides in preventing postoperative peritonitis involves the adminis-

tration of sulfadiazine systemically to the patient for forty eight hours before operation and for five to seven days after operation. Here the objective is to provide bacteriostatic concentrations of sulfonamide within the structures of the bowel wall and within the peritoneum as well as within the fluid bathing the peritoneal surface. Although sulfadiazine is not noticeably bacteriostatic in tissue concentrations against colon bacilli and intestinal streptococci it apparently exercises some restraining effect on their ability to multiply and will be particularly effective in preventing growth of hemolytic streptococci and staphylococci should they be present in small numbers. Therefore sulfadiazine administered systemically fulfills an objective not met by succinyl sulfathiazole the effect of which is limited to the bowel lumen. Hence it is quite reasonable to employ these two types of prophylactic treatment concurrently in the same case. A third method of employing sulfonamides in preventing postoperative peritonitis is to introduce a sulfonamide in powdered form into the peritoneal cavity in the region of the suture line at the conclusion of the operation. Although many surgeons are quite enthusiastic about this method of using sulfonamides it seems probable that its effectiveness is due largely to the circulation of the absorbed drug in local tissue fluids and the amount and rate of such absorption is harder to control with local implantation than if the drug is administered by mouth or intravenously. Furthermore there is evidence that drugs implanted locally in powdered form tend to cause local foreign body reactions and adhesions unless used in very small amounts and carefully distributed and if a rapidly absorbed drug such as sulfanilamide is used the high concentration of drug in the portal circulation may injure the liver. Regardless of the sulfonamide chosen the total amount placed in the peritoneal cavity should not exceed 50 Gm. The use of the drug locally is not essential if sulfonamide is given systemically in controlled doses.

Peritonitis is also of importance as a complication of acute appendicitis and other acute infections of portions of the gastrointestinal tract. Administration of the drug cannot commence until the infection has

proceeded to a point where a diagnosis can be made but if there is evidence that the infection of the peritoneum has not been dealt with adequately by the operation alone or if evidence of early peritonitis exists sulfadiazine in doses of 40 to 60 Gm per day should be given during the immediate postoperative period. The drug may be given intravenously until it is possible for the patient to take it by mouth. Here again it is possible to use local implantation of powdered sulfonamide at the site of infection but for the reasons outlined in the foregoing paragraph it seems doubtful that local use alone should be depended upon. Furthermore this route of administration may actually be unnecessary if proper systemic treatment is carried out.

The treatment of established peritonitis should include the administration of sulfonamides. The principal objective here is to suppress the growth activity of bacteria on and beneath the peritoneal surfaces in the hope of minimizing the amount of toxic products of bacteria which the patient will absorb and in the hope of promoting the formation of localized abscesses which either will drain spontaneously or will be subjected to surgical drainage. In view of the consistently low mortality rates which have been reported from appendiceal peritonitis since sulfonamides have been introduced it seems probable that this treatment is of definite value if used as an adjunct to proper surgical management. Certainly the beneficial results appear to have heavily outweighed the occasional toxic reactions which have resulted from administration of sulfonamides to these patients.

The usefulness of penicillin in connection with peritonitis remains somewhat uncertain. In cases where persistence of active infection and toxemia is clearly due to the presence of gram positive organisms the administration of penicillin may aid in the final recovery of the patient. However if penicillin is not to be wasted in the treatment of such cases they should be carefully selected on the basis of clinical course and bacteriological signs.

It must be emphasized again that chemotherapy in peritonitis is nothing but an adjunct to surgical management and may never be employed as a substitute for early

operation, meticulous technique and careful preoperative and postoperative correction of physiological abnormalities.

Tenosynovitis—Acute infection of the tendon sheath presents a dual problem. In the first place this is a potentially invasive infection which if neglected may spread widely throughout the anatomical course of the structure and lead to disseminated sepsis. Also it tends to result in early destruction of the tendons which are of major functional importance. The invasive features of acute tenosynovitis can probably be dealt with adequately by carrying out the regimen outlined in the foregoing section on invasive infections. In this particular type of infection however it is usually desirable to resort to surgical drainage of the sheath rather early because persistence of elevated fluid pressure within the sheath tends to disturb the delicate blood supply of the tendon. If the patient is responding to chemotherapeutic treatment it may be unnecessary to carry out as radical and extensive an exposure of the sheath as has formerly been practiced but at least the sheath must be decompressed if spread of infection and destruction of tendon are to be minimized. Following operative drainage it may be desirable to employ topical application of powdered sulfonamide or penicillin. According to Florey and Williams the recovery of patients treated locally with penicillin occurs with strikingly greater rapidity than is seen in control cases in which treatment consists of surgery alone. Any method of treatment of this sort which serves to bring the active infection more rapidly under control should be of great assistance in effecting rapid restoration of function to the infected digits. Much of the disability frequently seen following these infections is probably due to the prolonged period of suppuration which often follows surgical drainage.

Cellulitis—Hemolytic Streptococcus Infections—The effectiveness of the sulfonamides is nowhere demonstrated more clearly than in the marked reduction in the frequency and severity of hemolytic streptococcal cellulitis which has occurred during the past few years. These infections which characteristically follow trivial wounds and in the untreated form display a very ful-

minating course ordinarily respond very promptly to the regimen just outlined for acute invasive infections. If treatment is commenced early the development of acute suppurative lymphadenitis may be aborted though in some cases the lymph nodes draining the infected area will become abscessed and will require surgical drainage.

Staphylococcus Aureus Infections—Chemotherapeutic treatment of acute staphylococcal infections of soft tissues including boils, carbuncles and similar infections in operative wounds is of value chiefly in preventing the spread of infection from the site of origin and in minimizing the amount of tissue destruction. Penicillin is clearly the drug of choice for use in such cases and should be given in doses of 100 000 to 150 000 units per day depending upon the severity of the infection. Even penicillin will rarely succeed in preventing the development of some degree of tissue necrosis and suppuration. This necrotic tissue either must be left to drain spontaneously or preferably should be removed surgically. After operation the local use of sulfonamides in the infected wound is of doubtful value because the necrotic tissue inhibits the bacteriostatic action of the drug. Penicillin appears to offer much more promise as a local application to infected wounds of this type but its efficacy will be greatly increased if the amount of slough and necrotic tissue is minimal. A major need in surgical therapeutics which has not yet been met is for an agent which will rapidly and effectively cause the separation of slough from wounds of this sort thereby considerably hastening the healing. Such an agent would probably do more to shorten the healing time of infected wounds than any measure calculated only to attack the bacteria. This is a matter which deserves further careful research in the field of applied biological chemistry and physiology.

Recurrent furunculosis is a serious clinical problem which is encountered with considerable frequency. These recurring crops of boils may be confined to one area such as the back of the neck or the axilla or may appear widely distributed throughout the body. It is not clear yet whether a course of penicillin treatment will serve to prevent the development of succeeding

crops of furuncles but in serious cases such treatment will deserve a trial. Dosages of 50 000 to 100 000 units per day should be continued over a period of ten to fourteen days. Another method of special treatment which has shown encouraging results involves the use of staphylococcal toxoid. Since the dosage varies with the particular type of toxoid used no attempt will be made here to outline specific treatment with this agent. Price²¹ has recently advocated prolonged scrubbing of the skin with ethyl alcohol (strength 70 per cent by weight) as a means of preventing recurrences of boils. This is of great assistance in cases where the recurrences are in a limited anatomical region such as the neck or axilla. Gentle scrubbing with alcohol should be continued for fifteen to twenty minutes and repeated daily for several days. Alcohol used in this way serves to reduce the number of pathogenic staphylococci in the skin and may remove them altogether.

Gas Gangrene—Chemotherapy of established gas gangrene is limited in its effectiveness as long as gangrenous tissue is present. Obviously neither sulfonamides nor penicillin will gain access to bacteria which are proliferating in gangrenous muscle and fascia to which the blood supply has been shut off. Therefore one should never consider that the administration of either sulfonamides or penicillin alone will constitute adequate treatment for an established infection in this category. Furthermore these chemotherapeutic agents will not serve to neutralize the lethal and necrotizing toxins elaborated by the clostridia and they are therefore not substitutes for a specific antitoxin. The principal basis for the use of chemotherapeutic agents in gas gangrene is to prevent the spread of these organisms and of the staphylococci and streptococci which frequently accompany them into healthy tissue peripheral to the gangrenous focus. In treatment of these cases primary emphasis should be assigned to large doses of antitoxin and to thorough surgical removal of all necrotic tissue with resort to amputation when necessary. Penicillin or sulfadiazine in this order of preference may then be administered as in any acute invasive infection. Local treatment of the wound following debridement or amputation

may consist in irrigation with penicillin but at present there is substantially greater evidence in favor of the use of zinc peroxide. This is a white insoluble powder which when prepared in suitable form and suspended in water will liberate oxygen over a period of many hours. It is applied to the wound on packing which has been saturated with a creamy aqueous suspension of the powder, the wet dressing then being sealed in with a thick layer of petrolatum gauze in order to prevent evaporation of the water and subsequent crusting of the dressing. In the presence of an active infection of this type these dressings should be changed daily so that the wound may be inspected for evidence of further spread of gangrene. Zinc peroxide dressings will be of value only in cases where the necrotic tissue has been completely excised. (For further details of this subject see the chapter by Meleney on the Relationship of Bacteriology to Surgery.)

Other Anaerobic Infections.—Soft tissue infections occurring in wounds adjacent to any portion of the gastrointestinal tract from mouth to anus may contain pathogenic anaerobes of various types, chiefly anaerobic streptococci, fusiform bacilli and bacteroides. Almost invariably many aerobic bacteria, such as hemolytic streptococci, staphylococci or gram negative bacilli are present in association with these anaerobes. It is probable that the anaerobic bacteria depend for their pathogenicity upon a symbiotic relationship to these other organisms, a point which has been well emphasized by Meleney. These anaerobic organisms are as a rule comparatively resistant to the action of chemotherapeutic agents including both the sulfonamides and penicillin. However, if wounds containing these organisms are subjected to careful surgical debridement and if penicillin or sulfadiazine is given in doses adequate for invasive infections, it may be possible to break up the symbiotic relationship by eliminating gram positive cocci which are susceptible to chemotherapy and thereby to facilitate healing of the wound and recovery of the patient. The same principle may be applied in the treatment of various types of chronic progressive ulcers which are discussed by Meleney in another section of this volume.

Osteomyelitis.—*Chronic Osteomyelitis.*—The treatment for the acute stage of hematogenous osteomyelitis has already been outlined in the section on treatment of acute invasive infections. Therefore here one is concerned chiefly with the management of the local bone focus. To meeting this problem penicillin has been of outstanding usefulness. In the first place penicillin administered during the acute phase of the disease is more effective than sulfonamides in achieving early subsidence of the evidences of acute infection. If penicillin treatment is continued after subsidence of fever and of signs of local inflammation at the infected site, the development of x-ray evidence of bone destruction may be considerably delayed. However, because the bone destruction in osteomyelitis is due to early loss of the blood supply of the involved area of bone, it is quite likely that breakdown of the bone will eventually show itself in the x-ray, subsequently if penicillin treatment is discontinued a flare up of active infection may occur in this region. X-ray evidence on bone decalcification does not alone constitute a reason for surgical intervention. If other evidence of active infection appears, it will often be necessary at some point during the convalescence of the patient to resort to surgical drainage of such areas of sequestration as may ultimately appear. At this time sequestra if present and chronically infected granulation tissue are removed. Administration of penicillin should be commenced two or three days before such an operation in order to protect the tissues against spread of infection consequent to the trauma of operation. On the basis of experience to date, which is still admittedly limited, it does not seem to be necessary to carry out the radical removal of healthy bone which is required in the classical Orr treatment. The reason for this is that if penicillin is continued for two or three weeks after operation, all staphylococci or streptococci will usually disappear from the wound exudate and the wound will fill with uninfected healthy granulation tissue. In the absence of any acute infection it may even be possible to employ primary closure of these debrided wounds, though experience is as yet inadequate to justify recommending such a course. However, since

a chemotherapeutic agent is at hand which is capable of producing such profound bacteriological changes it is not unreasonable to hope that these preliminary impressions will receive confirmation through extended experience. If primary closure of these wounds is possible an enormous saving of time and disability will result.

Infection in Compound Fractures—The problem of treating infection in compound fractures is essentially similar to the treatment of chronic osteomyelitis secondary to a primary hematogenous infection but with two important differences particularly if the fracture was originally due to external violence. First fractures of this type are frequently comminuted and an important factor in persistence of the infection may be the existence of devitalized fragments of bone which serve as foreign bodies. In addition foreign bodies of other types including clothing and fragments of projectiles may be present. Second many of these infections are polymicrobial in origin and may contain gram negative organisms and varieties of gram positive bacteria which are resistant to penicillin. These differences between infections in bone which are secondary to trauma and those which are due to hematogenous infection necessitate some modification in therapeutic management from that outlined in the foregoing section. In the first place surgical intervention must be somewhat more radical in scope in order to make certain that all foreign bodies have been removed. In the second place the result of preoperative penicillin therapy may be less satisfactory in the presence of varieties of drug resistant bacteria. Lyons² observed that postoperative closure of these wounds can be carried out successfully when all of the bacteria present were susceptible to penicillin treatment but when penicillin resistant anaerobes and other bacteria were present it was necessary to carry out the orthodox Orr treatment until the latter types of organisms had disappeared. He observed also that penicillin therapy which was continued without the use of surgical cleansing of the infected tissue would frequently result in healing of draining sinuses but that in such cases a later recurrence of local infection was to be expected. In this respect the experience of

Lyons with military casualties has been similar to the experience of surgeons who have dealt primarily with civilian problems.

Although the immediate results of combined surgical and penicillin treatment in chronic infections in bone have been highly encouraging it must be pointed out that final evaluation of this treatment must be based upon several years of follow up study. Bone may harbor quiescent infection for many years and the rapid healing which occurs with penicillin treatment is not necessarily indicative of complete eradication of bacteria from the lesion. Present results are sufficiently favorable to warrant wide use of this method and it is reasonable to expect that results will be far superior to those obtained with previous methods of management. At the same time one must preserve a guarded prognosis in respect to the end results of this treatment.

SPECIAL PROBLEMS IN CHEMOTHERAPY

In several of the foregoing sections some references have been made to the local use of chemotherapeutic agents in treating infections usually as an adjunct to chemotherapy by systemic routes. Recommendation has been made for the local use of penicillin in the treatment of empyema, meningitis, suppurative arthritis and infections of soft parts and bone but always in conjunction with the employment of such surgical procedures as may be required to afford adequate drainage of the lesion and removal of whatever pus and slough may be present. Zinc peroxide has been recommended for topical use in treating wounds infected with anaerobic bacteria but again only after adequate surgical procedures have been performed. The problem of the local use of antibacterial agents is a very complicated one therefore it seems appropriate to consider in the following sections some of the special matters which are pertinent to the local use of drugs both in the treatment of established infections and in the prevention of infection in wounds.

"Antiseptics" in the Treatment of Infected Wounds—The phase of chemotherapy which has received principal attention from surgeons during the past century has related to the use of antiseptics in the treat-

ment of localized infections of soft tissues and bone. Ever since Lister's use of carbolic acid to reduce the number of bacteria in wounds a practice which ushered in the era of modern surgery much attention has been given to the development of drugs which when applied to wounds would destroy the bacteria and therefore presumably hasten both the disappearance of infection and the ultimate healing. Literally hundreds of chemical substances have been tried out to meet this end. During the last thirty years the antiseptics which have received particular attention included various mercurial agents—bichloride of mercury ammoniated mercury mereurochrome metaphen and merthiolate a number of dyes—acriflavine proflavine gentian violet and propamidine and hydrogen peroxide zinc peroxide Dakin's solution (sodium hypochlorite) zinc chloramide and iodine. None of these agents may be administered by mouth or parenterally with any prospect of influencing infection in a local area either they are too toxic or are not absorbed or they are inactivated as soon as they come in contact with the protein in blood plasma or tissue fluid. Such usefulness as any of them may possess is limited to situations where they may be used topically either applied directly to an open infected wound or perhaps injected into an infected serous cavity such as the pleura or a knee joint. In general the results from local wound therapy of this sort have been disappointing and for the following reasons:

- 1 The chemical agent reacts as promptly with the protein of the wound exudate as with the bacteria so that the antiseptic effect so clearly demonstrable *in vitro* is of little significance within the wound.

- 2 The chemical agent is toxic to leukocytes and therefore interferes with the local operation of natural mechanisms of defense against bacteria. It may be said categorically that the beneficial antiseptic action of any drug will be more than counterbalanced if the drug has a toxic action on leukocytes.

- 3 The drug has a toxic action on host tissue and therefore tends to add to the amount of necrotic material in the wound—material which provides the best medium for growth of bacteria. By the same process the drug delays wound healing and interferes with formation of granulation tissue

so that even if the number of bacteria in the wound is reduced the cost in delayed wound repair from using the drug is greater than is justified by the immediate results.

It cannot be denied that under certain special conditions infected wounds treated with one or the other of these antiseptics will appear to heal more rapidly than could have been expected had specific treatment not been used; however whenever this happens the dresser of the wound should ask himself the following questions:

- 1 Would the wound have done as well had some neutral material of similar physical consistency but of no specific antibacterial effect been used in similar fashion?

- 2 If the agent was genuinely effective and if its value could be substantiated in controlled studies could one be certain that its value was due to its antibacterial action or was it perhaps due to some other simultaneously operative function such as stimulation of leukocyte reactions acceleration in volume flow of lymph into the wound or hastening of the separation of slough?

During World War I there was great enthusiasm for the Carrel Dakin treatment of wounds which involved the continuous irrigation of wounds with hypochlorite solutions through small rubber tubes carefully placed in the wounds so as to permit the widest contact between the fresh solution and all of the ramifications of the wound. It still remains doubtful whether the good results of dakinization were due to the meticulous dressing technique required the dissolving action of the alkaline Dakin's fluid on slough the mechanical washing effect of the solution which tended to remove wound debris or the irritant action of the hypertonic fluid which evoked the outpouring of large quantities of healthy lymph and fresh leukocytes. Each of these explanations for the usefulness of the Carrel Dakin treatment has received support by different groups of investigators. Similarly the value of zinc peroxide may actually reside entirely in the high and prolonged concentrations of peroxide and oxygen which it provides to the wound but on the other hand its usefulness may be due in no small part to the abundant exudate which its application to a wound evokes or it may be due to the fact that the insoluble porous particles of zinc per-

oxide are an excellent medium for adsorption of bacterial toxins in the wound

Therefore the surgeon must remember that the application of an antiseptic chemical to a wound sets in motion an exceedingly complex chain of phenomena that action against the bacteria is only one item in the sequence and that more often than not the net result is unfavorable rather than favorable to the rapid healing of the wound

The local treatment of an infected wound is never simply a problem of destroying the bacteria on the wound. For one thing the bacteria which are responsible for the persistence of the lesion are not likely to be located only on the surface of the wound where they come into contact with a locally applied agent; they are beneath the surface of the wound beneath an intervening layer of fibrin or of devitalized tissue through which the antiseptic agent may not penetrate. Furthermore persistence of the infection may be due not so much to an vital parasitic quality of the bacteria themselves as to the presence of fundamental alterations in the local wound physiology which are detrimental to the healing process and provide a medium for saprophytic growth of bacteria. For example the problem of treating the infection in a deep burn is primarily the problem of effecting separation of the devitalized burned skin and only in part the direct attack on infecting bacteria

In attempting to meet the problems of the infected wound it is easy to be misguided into focusing attention largely on the bacteria but progress toward improving therapy of such lesions can be met only through recognition of the true nature of the process and of the relative importance therein of tissue alteration on the one hand and infection on the other

Penicillin enjoys more promise in the local treatment of infected wounds than any of the agents hitherto employed because it is innocuous to tissue; it is not inhibited by pus and products of tissue degradation and it is absorbed from the surface of the lesion. It has been applied in the form of powder solution and ointment but the best technique for its local use has not yet been developed

Prophylaxis Against Wound Infections
—The use of chemotherapeutic agents in

the prevention of infection in accidental wounds and burns has received major attention in civilian and military surgery during the past few years. It has seemed entirely reasonable to expect that the presence in wound fluids of bacteriostatic concentrations of chemotherapeutic agents would tend to prevent multiplication of contaminating bacteria within the wound and thus prevent the development of infection. The importance of infection in wounds of military casualties has given particular impetus to investigation of this subject

There are two logical ways of employing chemotherapeutic agents in preventing wound infections. The first involves the systemic administration of a drug as a means of achieving its bacteriostatic concentration in the wound fluids and especially in the tissue immediately adjacent to the wound. The second route of administration involves local implantation of the drug into the wound. With both methods of administration it is obviously important to initiate treatment at the earliest possible moment after injury in order to obtain the bacteriostatic effect before opportunity for proliferation of contaminating bacteria has developed. With these objectives in mind the United States Army has provided soldiers and medical corpsmen with tablets of sulfadiazine to be taken internally immediately after injury is sustained; they are also supplied with a powdered sulfonamide usually sulfanilamide in sterile packages for local implantation beneath the emergency dressing. It is hoped that such treatment will cause each patient to arrive at the casualty clearing station or hospital in a non-infected condition and that surgical treatment may thereby be rendered more effective. Similarly there has been a growing practice among civilian surgeons to employ local and systemic chemotherapy in the prevention of infection in compound fractures and contaminated operative wounds such as those occurring with operations on the gastrointestinal tract. The evaluation of these methods of prophylaxis must be based upon two different criteria. First does chemotherapeutic prophylaxis reduce mortality by preventing fatal septic complications of wound infection? Second does it prevent local infection within the wound itself? The

evidence from both military and civilian quarters justifies an affirmative answer to the first question. However the answer to the second question can be expressed only with definite qualifications. Although many individuals remain enthusiastic concerning the effectiveness of sulfonamides in preventing wound infection there is a good deal of evidence that such success is obtained only under special conditions. In the opinion of the author all of the evidence tends to support the continuation of the practice of administering sulfadiazine or penicillin systemically to all individuals with major accidental wounds including compound fractures. This practice is justified on the basis of the ability of the sulfonamide to prevent fatal infection regardless of whether it may be limited in its ability to prevent infection as a complication in the healing of the local wound. Furthermore it would seem that theoretical and practical considerations support the practice of applying sulfonamides locally as soon as possible after injury and for as long as the wound remains open. Since most war wounds are permitted to remain open for at least a week before any question of closure is permitted it is desirable to continue the present military procedure. However a study carried out in civilian hospitals on wounds which were for the most part subjected to early primary closure has failed to yield evidence of the value of sulfonamides in preventing local wound suppuration; in fact the incidence of infection in wounds of soft parts and compound fractures was actually higher when sulfonamides were used than it was in the control cases in which no drug was given. This study which was reported in a preliminary way by Meloney³ has led to conclusions which are definitely at variance with the opinions of many civilian and military surgeons whose attitudes are based upon general clinical impressions rather than controlled observations.⁴

A certain amount of the confusion which has arisen is due to the fact that different investigators have been concerned in their study and practice with different types of wounds. Therefore in order to clarify the status of prophylactic chemotherapy in relation to contaminated accidental wounds these will be placed in four principal cate-

gories and the place of chemotherapy in relation to each particular type will be discussed. Since there will be general agreement that either sulfadiazine or penicillin should be administered *systemically* in all cases of severe wounds as a means of preventing fatal septic complications this discussion will be concerned largely with the *local* use of chemotherapeutic agents.⁵

Fresh Contaminated Wounds Just After Injury—These are the types of wounds with which the medical officer or hospital corpsman is principally concerned on the battle field and in the first aid station. They characterize also the problems confronting the ambulance surgeon and the medical attendant in the receiving ward of the civilian hospital. The wound is contaminated and is therefore likely to become infected. But infection is not the only problem; hemorrhage and shock may also be present and these considerations require primary attention. Fractures and penetrating wounds of the chest and abdomen present certain special problems. Another dominant consideration will always be to transport the patient to a suitable operating theater with the greatest possible speed. However the time interval between first aid treatment and definitive surgical treatment may vary from a few minutes to many hours or even days. The objective which demands the use of prophylactic chemotherapy is to prevent proliferation of bacteria on the wound surfaces during this interval. The effectiveness of topically applied sulfonamides will for a few hours not be impeded by the presence of proteolytic products of tissue break down in the wound. Since the wound is not closed no question of possible interference of the drug with wound repair arises. Therefore the situation calls for the local implantation of the form of sulfonamide which is most readily available. Sulfanilamide may be used in amounts up to 15 Gm. in no individual case; sulfathiazole which is only slightly below sulfanilamide in the order of choice may be used in amounts up to 10 Gm. In either case, the drug should be distributed as widely as possible throughout the wound area even though it is introduced only at one part of the wound. Sulfathiazole and sulfadiazine are limited in this respect by their comparative insolubility but they enjoy compensat-

ing advantages through somewhat longer persistence in the wound. The locally applied drug serves the purpose of supplementing the bacteriostatic action of the sulfadiazine or penicillin which may be administered by systemic routes. At the time of this writing experience with the local use of penicillin in such cases has been inadequate to provide a satisfactory basis for its evaluation. It is doubtful if it will be of much value for this purpose until some method is discovered of causing it to be retained within the wound for at least a few hours. When applied in the form of an aqueous solution its effect is exceedingly transient.

Contaminated Wounds Which Have Been Debrided or Trimmed and Left Unstitched Possibly in Anticipation of Secondary Suture—This category includes most of the wounds treated in front line military hospitals and also those wounds in civilian hospitals which have not been subjected to primary closure. Here the degree of wound contamination has been reduced to a minimum by removal of severely damaged tissue and careful removal of foreign bodies. It is pertinent in this connection to quote Sir David Wilkie to the effect that too vigorous scrubbing of a wound surface is "The joy of the housewife but the agony of the biologist." Usually the wound will be packed loosely with some non-adherent material such as petrolatum gauze and if the wound is of an extremity a plaster cast or pressure dressing will be applied. In a wound treated in this way there would seem to be a decided advantage from attempting to delay proliferation of bacteria beneath the dressing by the local implantation of a sulfonamide. Here again the local drug is employed as a supplement to a sulfonamide or penicillin administered by systemic routes. Since the wound is left open to granulate there is no major question of interference with wound repair by the topically applied drug and even the less soluble compounds such as sulfathiazole may safely be employed for this purpose. If wound debridement has been adequate the drug may be brought into contact with all portions of the wound. Even though reports of controlled investigation on wounds of this type are not yet available to establish the superiority of end results in wounds so treated yet when these

are compared with wounds not implanted with sulfonamides continuation of this practice is to be recommended. It can do no harm and it appears on rational grounds to be entirely justified.

Wounds Which Have Been Debrided or Trimmed and Closed Primarily With or Without Tension—A special set of problems regarding the local use of sulfonamides arises in connection with the wound which is to be subjected to primary closure. Since current military practice is strongly opposed to primary wound closure this is not a matter of major concern in war surgery except in connection with wounds of the scalp, abdomen and thorax in which primary closure is necessitated for protection of underlying structures. It is a problem which arises very commonly in civilian hospitals where primary closure of accidental wounds is now a common practice. Civilian wounds are associated with less destruction of tissue than military wounds and are usually treated surgically within one or two hours of the time of the accident. Furthermore unlike many military patients the civilian patient may be kept under continuous clinical observation by the surgeon so that the development of infection in the closed wound may be recognized more promptly than is possible in war wounded who are being transported to fixed hospitals in the rear. Several factors may tend to interfere with the ability of sulfonamides to prevent infections in closed wounds. In the first place it must be remembered that neither locally applied sulfonamides nor penicillin will destroy bacteria which are retained within the closed wound. The drugs may greatly retard their tendency to proliferate and when conditions in the wound are favorable they might check bacterial growth until clearance by phagocytes has been achieved. However local activity of the drug will not continue for more than a few days and the time must come when the bacteriostatic action ceases to operate. At this time bacteria which have not yet been destroyed by the leukocytes will be able to produce local infection. In the second place, the sulfonamides possess only a limited bacteriostatic effectiveness against the staphylococcus which is present in four fifths of infections of accidental wounds. Third there may be present considerable amounts of

tissue break down products which will be retained in the wound until they are absorbed and which during their presence will tend to inhibit the bacteriostatic action of sulfonamides. The amount of such inhibitors will vary directly with the amount of devitalized tissue left in the wound after debridement or produced by the constricting effect of sutures and ligatures. Experience has shown that the incidence of infection in wounds closed under tension is far higher than in wounds closed without tension.³ The use of sulfonamides will not diminish the likelihood that infection will develop in wounds of the former category. Fourth, there is some evidence that the local implantation of the less soluble sulfonamide derivatives such as sulfathiazole and sulfadiazine interferes with the rate and quality of wound repair. This deleterious action of sulfonamides can be minimized by resorting to the use of sulfanilamide or by employing only small quantities of the more insoluble drugs. The drug must be well distributed on the wound surface and never applied in massive aggregations. The amount required to produce a light frosting of the surface should never be exceeded.

What has been said of the use of local sulfonamides in preventing infection in neer dental wounds may be applied with perhaps greater effect to the prevention of infection in contaminated abdominal wounds associated with operations on the gastrointestinal tract. In an earlier paragraph skepticism was expressed concerning the need for local implantation of sulfonamides within the peritoneal cavity in such cases. However, there is mounting evidence that the local use of small quantities of sulfonamide in the abdominal wound itself will tend to reduce the likelihood of postoperative infection. This may be due to the fact that such wounds do not require closure under tension; they contain minimal quantities of devitalized tissue and the bacterial flora may be generally more susceptible to the action of sulfonamides than are the organisms introduced under conditions of accidental injury.

Chemotherapy in Burns—Sulfonamides and penicillin have been employed in a variety of ways to reduce the incidence of infection in burns. Here again the primary consideration is to prevent the development

of fatal sepsis; therefore it is most important to administer the chemotherapeutic agent by systemic routes. Sulfadiazine must be given with some caution to the burned patient because of the possible association of kidney damage but penicillin may be given without fear of toxic consequences. Chemotherapeutic agents administered systemically will have little effect on the proliferative activity of bacteria on the burn surfaces but will prevent them from invading the underlying tissue. The amount of surface infection will tend to vary directly with the amount of devitalized tissue and will thus be much greater in third degree burns than in superficial second degree burns. Infection of this type may not lead to fatal consequences and in a sense may be considered as a saprophytic type of infection. However, it may be a factor in toxemia and may interfere with the successful application of skin grafts. The question has naturally arisen therefore as to whether the local application of sulfonamides or penicillin to the surface of the burn will reduce the severity of such surface infection.⁷ The study reported by Meloney failed to indicate that sulfonamides are of particular value when used in this way. Some discrimination is required in selecting the types of sulfonamide preparation to be used on the surface of the burn. If comparatively soluble sulfanilamide powder is used on a large burned area the rapid absorption of the dissolved drug may result in toxic concentrations in the blood. The rate of absorption of sulfanilamide may be retarded by incorporating it in an oily base but very probably its effectiveness is largely nullified when such a barrier against absorption is provided. Sulfathiazole appears to be absorbed much less rapidly from the surface of the burn and has been employed without toxic effects by Gurd, Ackman, Gorrie and Pritchard⁸ in the form of an oil in water emulsion. Sulfadiazine dissolved in triethyl anolamine has been recommended by Pickrell⁹ and although difficult to apply and incompatible with the use of the currently favored pressure dressings this preparation has appeared to be quite effective in preventing infection of superficial burns.

The local use of sulfonamides in burns does not seem to merit the emphasis it has received in many quarters. The principal ob-

jectives in local burn management should be the early application of a protective pressure dressing and encouragement of the separation of slough at the earliest possible time so that skin grafts may be applied to a healthy base before opportunity for the development of serious surface infection has arisen. If the local employment of sulfonamides does not interfere with these main objectives there is no reason for not employing them as one element in the local therapy.

CONCLUSION

One unfortunate consequence of the prevailing interest in the use of chemotherapeutic agents to prevent infection in wounds and burns has been the trend toward an erroneous direction of emphasis in wound management. Regardless of the particular type of wound involved it should constantly be remembered that the bacteria in the wound and the effect on these bacteria of the chemotherapeutic agent is only one of a great many factors which enter into the achievement of the end result. More important than the use of chemotherapeutic agents is the provision of conditions which will be optimal for the healing of the wound. The introduction of the sulfonamides and penicillin has not made possible the abandonment of any of the principles of surgical management which experience has shown to be indispensable in the achievement of satisfactory wound repair.

TETANUS

Definition.—Tetanus is a disease of man and certain lower animals characterized by local spasm or general convulsive contractions of the voluntary muscles due to the action of a poison produced by a specific bacterial agent, *Clostridium tetani*.

Historical.—The dramatic manifestations of this disease and its high mortality very early attracted the attention of medical observers so that fairly accurate descriptions are found in the older writings particularly those of Hippocrates¹ and Aretaeus.² In the early history of man two factors relating to the incidence of this disease are of considerable importance namely the frequency of bodily injury and the close contact of man with domestic animals and the soil. It was not until 1800³ that the infectious nature of tetanus was suspected. In 1860 Richardson⁴ suggested transferring the disease from man to animals by inoculating animals with blood from patients who had died of the disease. Success was not attained however until 1884 when Carle and Rattone⁵ produced the disease in animals by transferring a portion of a human wound infected with tetanus. In the same year Nicolaier⁶ produced typical spasms by injecting garden soil into animals. He then observed a bacillus which he considered to be the cause of the disease. Two years later Rosenbach⁷ described the characteristic spores and attempted to obtain the organism in pure culture. The latter was first accomplished by Kitasato⁸ in 1889 when he heated to 80° C for forty five minutes a mixed culture of bacteria obtained from a patient with tetanus. He then demonstrated that the causative organism was an anaerobic spore forming bacillus. In the same year von Behring and Kitasato⁹ established the toxic nature of the disease by inoculating with pure culture filtrates and producing antitoxin in animals. The discovery of the organism was followed by extensive research with regard to its cultural characteristics, the production of its toxins and the mechanism of its pathogenicity.

The Etiological Agent.—The *C. tetani* is a gram-positive spore forming bacillus which is strictly anaerobic. The spores are terminal and round and are thus easily distinguishable from the sporulating anaerobic bacilli of the gas gangrene group. The organism grows only in a medium or in an environment with an oxidation reduction potential ranging between 0 and 15. It grows best at 37° C in a medium having a pH of 7 to 7.6. Stab cultures in gelatin or agar produce a typical "inverted fir tree growth" while on blood agar plates the culture spreads as a thin film. It does not

ferment sugars or digest protein. Its various forms may be divided into a number of groups which differ in their agglutination reactions (3 main types and 4 other rarer types) but all these groups produce the same toxin. This has at least two fractions one being hemolytic and the other neurotoxic¹⁰ possibly one fraction causes convulsion and the other death.¹¹

The organisms are essentially saprophytic. They are frequently found in the feces of horses, cattle and sheep but to a considerably less extent in the intestinal tract of man unless he has been fairly recently in close contact with domestic animals. A study of the fecal discharges of urban dwellers revealed an incidence of less than 5 per cent but a similar study of a group of farmers or of soldiers who had recently returned from World War I yielded an incidence of 30 to 35 per cent of these organisms.^{11, 12}

Tetanus organisms in pure culture are practically harmless when injected into the normal tissues of susceptible animals but if the tissues are injured by mechanical or chemical means or by concurrent infection with other bacteria the tetanus bacilli multiply and produce toxin.

Natural Infection.—Portal of Entry.—The experimental observation just mentioned probably applies to the disease as it develops clinically in man and in animals because in almost every case there is some evidence of tissue injury or concomitant infection. The organism may enter the body through a gunshot or knife wound, a compound fracture or any gangrenous or traumatized portion of the skin, including a bed sore. It may also enter through more trivial injuries, such as insect bites or stings, bites of animals, blisters from burns or other irritants, extraction of teeth or even trivial scratches.

Development of the Infection.—When the organisms have been introduced and have found conditions favorable for their growth, they multiply readily in situ but usually do not invade the body. They probably do not multiply as rapidly as other organisms because even in well established infections it may be difficult to recover them from the lesion. Occasionally they have been found in regional lymph glands but not in the blood stream or in distant organs or tissues. They produce their disease in a manner similar to that of diphtheria bacilli by developing a powerful exotoxin which is absorbed and carried to the susceptible tissues, where it produces the characteristic symptoms.

Period of Incubation.—This varies remarkably and represents the time it takes

the organisms to grow and produce their toxin plus the time it takes for the toxin to attack the susceptible tissues. A few cases have been reported in which the symptoms appeared within twenty-four hours of the injury. In other cases the period of incubation has been prolonged over a period of weeks and one case has been reported in which the characteristic features of the disease did not appear for two hundred and thirty-nine days. The greatest number of cases develop in seven to fourteen days.

Symptomatology—There are apparently two characteristic groups of symptoms depending to some extent on the location of the portal of entry and the manner and speed with which the toxin is produced and absorbed. The first is called local or ascending and the second general or descending tetanus. In local tetanus there is stiffening or twitching of the muscles in the region of the wound which may be so mild that it is not recognized as a manifestation of tetanus. It may pass off spontaneously or may gradually increase in severity and range until it spreads upward involving the whole body.

In the descending type the symptoms begin first in the small muscles of the face with stiffening of the masseter muscles which may progress until it is impossible for the patient to open his mouth (lock jaw). The muscles of the face may pull back the corners of the mouth giving a grimace called the risus sardonicus of Aretaeus. The pharyngeal muscles may be involved making it difficult for the patient to swallow. The muscular spasm gradually spreads downward to involve the muscles of the neck, chest, back, abdomen and extremities. In both the ascending and descending type when there has been extensive stiffening of the muscles the patient exhibits a series of clonic or tonic contractions of the muscles which may start in small groups and gradually spread until the whole body is thrown into a violent convulsion. Such attacks are frequently started by trivial external stimuli, a mere touching of the body with the hand or with the bedclothes, a jar of the bed, a sudden increase of light in the room or even a loud noise. The convulsions may increase in frequency until they are almost continuous and then the inability of the

patient to relax the diaphragm or the external muscles of respiration prevents the intake of air and asphyxia supervenes. It is thought that the frequent and more or less continuous contraction of the muscles produces a large quantity of lactic acid and consequent acidosis which is incompatible with life but death is essentially due to suffocation. The contractions of the muscles of mastication may be extremely painful because of the pressure exerted on the teeth but the cramp of other muscles is usually not so distressing except for their psychological effect on a very clear mental state.

Pathology—When examinations are performed on man and animals after death due to tetanus no pathologic lesions can be found except in experimental animals to which tremendous doses of toxin have been given. There is apparently no death of the cells of the central nervous system which are rendered hyperactive by the toxin nor of the muscle cells which are found grossly to be in a contracted state. In human beings in whom the disease has been prolonged through a period of several days and to whom it has been difficult to give proper nourishment there is a wasting process in the various organs and tissues of the body but no specific pathologic changes can be demonstrated.

Abel and his co-workers¹² have shown that when a minimal lethal dose or a sublethal dose of toxin is injected by any route into experimental animals it is rapidly taken up and fixed both by the highly specific tissues and by the non-responsive tissue of the body. In these cases although the animal dies no toxin can be found in the blood and lymph and no toxin can be detected as such in the tissues of the body. If more than one minimal lethal dose is injected the excess can soon all be found to be present in an unchanged state in the blood and lymph. Any toxin in the tissues is then due entirely to the toxin present in the contained blood and lymph and no greater concentration is found in the central nervous system in the nerves or in the muscle than is proportionately present in the other organs according to their blood supply.

Treatment—Rationale of Treatment—It will be seen that the rational treatment of tetanus depends on an accurate knowl-

edge of the pathogenesis of the disease This is not yet entirely clear in spite of the clinical and experimental investigations carried on over a long period of time Until recent years the theory has been generally accepted that the toxin is produced locally in the region of the wound and that it reaches the central nervous system only by passing up the motor nerves to the anterior horn cells of the cord and thence spreading both up and down within the cord and backward to involve the sensory nerve cells It was thought that whatever toxin was absorbed by the blood and lymph was distributed by the arterial circulation to the various muscles of the body and then in turn absorbed by the axis cylinders of their motor nerves The absorption was said to be accomplished either by protoplasmic streaming within the axis cylinder by way of the perineurial lymphatic ducts or up through the interfibrillar channels The beginning in the face and jaw muscles of the symptoms of descending or general tetanus was explained by the fact that in these muscles the shortest route to the central nervous system was found Local tetanus in the muscles near the portal of entry was explained by the absorption of the toxin by the motor nerves in these muscles with contraction occurring as soon as the toxin reached the motor nerve cells in the cord¹⁴

However a number of investigators brought forth clinical and experimental evidence to cast doubt on this theory¹⁵ and more recently Abel and his associates have brought strong evidence to light which seems to refute this conception They have called attention to the fact that there is no such thing as protoplasmic streaming within the axis cylinder of the nerves and that the perineurial lymphatic ducts pass upward to regional lymph glands and not to the spinal cord Likewise there is no possibility for the toxin to pass up through the tissue spaces between the fibers in a nerve bundle They believe that local tetanus is produced by direct action of the toxin on muscles in the neighborhood of the distributing focus and that all the rest of the toxin is rapidly taken up through the blood capillaries and lymphatic vessels into the blood stream and distributed throughout the body through the arteries They believe

that there is no blood brain barrier' preventing the passage of the toxin into the susceptible central nervous system tissue and no barrier between the blood and other susceptible tissues They do not offer any satisfactory explanations for the order in which symptoms appear in the descending form of the disease These important studies have been confirmed and are being continued by Piror¹⁶

Prophylactic Treatment—**OPERATIVE**—It is evident from the foregoing brief review of the pathogenesis of the disease that it is of the greatest importance to prevent the evolution of a lethal dose of the poison When any condition exists or when any wound is produced which is likely to provide conditions favorable for the introduction and the growth of *C. tetani* treatment must be instituted which will make the establishment of this organism difficult if not impossible The surgical procedure in the treatment of the wound requires the removal of all foreign bodies and devitalized tissue no attempt should be made to close the wound The margin of excision of course may have to be limited and a compromise may be necessary when the wound is in certain anatomical locations which make extensive excision of the part inadvisable as for example on the face

ANTISEPTICS—Various antiseptics have been recommended for use after the excision of the wound The most recent and probably the most important is zinc peroxide which not only inhibits the growth of all anaerobic organisms by producing a highly oxygenated environment but also has a detoxifying action on the toxin and yet does not injure tissue¹⁷ The use of penicillin in these wounds has been of such recent development that an adequate determination of its value has not yet been possible in a large series of cases but in vitro the growth of *C. tetani* is inhibited by penicillin

ACTIVE IMMUNIZATION—In recent years encouraging efforts have been made to produce active immunity in such persons as soldiers who are likely to be subjected to wounds contaminated with tetanus organisms It has been found that the injection of toxoid¹⁷ or antotoxin (toxin detoxified by formalin or alum precipitation) calls forth antitoxin in the body of the recipient It

tle or no response is seen after the first injection but if the second is given three to six weeks later there is a sharp rise in the antitoxin content of the blood serum. This is maintained for a variable period of months and gradually disappears. If however a third injection of toxoid is made three to six weeks afterward there is sudden development of antitoxin which seems to be adequate to combat the majority of natural infections with the organism. Thus if a soldier is immunized by three injections of tetanus toxoid and later sustains an injury another dose or series of toxoid injections is considered to be more effective as a prophylactic than a dose of tetanus antitoxin. The use of toxoid practically eliminated tetanus from the French army early in the present war. That the American and British forces have been similarly protected has been amply demonstrated by the low incidence of tetanus in the casualties so far reported.

SEROTHERAPY—Sufficient tetanus antitoxin should be administered to neutralize promptly any toxin which may be produced. The usual prophylactic dose of tetanus antitoxin is 1500 USP units which represents enough antitoxin to neutralize a minimum lethal dose for a 150 pound man. The relative value of these prophylactic measures cannot be accurately estimated and one can be sure that no single measure will prevent tetanus in all cases. It was demonstrated beyond the shadow of a doubt by the experience of army surgeons in the first World War that the routine use of antitoxic serum was of tremendous value. The high incidence of tetanus in the early days of the war when antitoxin was not available is compared with the minimal occurrence of the disease when the antitoxin was given as a routine measure amply demonstrated its efficacy. When conditions were maintained which favored the development of tetanus such as in compound fractures or retention of foreign bodies which it was impossible to remove it was found necessary to repeat this prophylactic injection every week or ten days until it was certain that at the conditions no longer existed. When secondary operative procedures must be carried out for war wounds it is likewise necessary to repeat the prophylactic injection

because the traumatism of tissue in which tetanus spores may be lying quiescent might reactivate the organisms and reestablish conditions favorable for their multiplication and the elaboration of their toxin.

Active Treatment—**OPERATIVE**—When the initial symptoms of the disease have appeared the first requirement is to remove surgically the focus of infection or the toxin factory. This requires complete excision of the wound and removal of all foreign bodies and necrotic or grossly infected tissue. No attempt should be made to close the wound.

ANTISEPTICS—After the surgical procedure the wound area should be flooded with a creamy suspension of effective zinc peroxide. By effective zinc peroxide is meant the medicinal grade of that product which has been dry sterilized according to instructions and which when added to sterile distilled water to the amount of 5 Gm in 50 cc will settle as a soft curdy precipitate leaving the supernatant fluid clear and will cause the evolution of oxygen within the first hour with continued evolution during the next twenty four hours. It is important to make certain of the contact of this creamy suspension with every part of the wound. In many cases it is necessary to pack the wound gently with fine mesh gauze or absorbent cotton soaked in the zinc peroxide suspension so as to keep the surfaces of the wound apart. The dressing should then be covered over with water soaked cotton and then with vaselin gauze to prevent evaporation.

CHEMOTHERAPY—Penicillin should then be given systemically at the rate of 200,000 units daily either continuously by intravenous or intramuscular drip or every two hours by intramuscular injection.

SEROTHERAPY—Further treatment is directed toward the neutralization of the toxin which has been distributed throughout the body. Potent antitoxin in measured USP or international units may be introduced subcutaneously intramuscularly intravenously or intrathecally and should be given in large quantities within the first twenty four hours. Although many of servers (Sherrington¹⁸ Nicol¹⁹ and others) advocate the intrathecal route Abel and others maintain that it offers no advantage be-

cause the antitoxin is rapidly absorbed in the blood stream from the spinal fluid and does not come in contact with the toxin already fixed within the central nervous system. There are no dependable statistics to prove whether or not the intrathecal injection is of value. During the last war Bruce⁹ gave some statistics for the British army showing that the mortality had been reduced from 57.7 per cent in 1914 to 1915 when tetanus antitoxin was not available to 19 per cent in the last period of observation (1917). This improvement was due not only to the prophylactic use of serum but to the improved surgical technique. But in the last 100 cases in which presumably the surgical technique was the same the men who had received prophylactic serum showed a mortality of 17.7 per cent and those who had not been given prophylactic serum a mortality of 28.5 per cent. One would suppose that in the active treatment of tetanus with serum better figures for recovery would be found for the group receiving large doses of serum on the first day in which symptoms appeared but such is not the case. In like manner if intrathecal injections of serum were of any special value one would expect a lower incidence of mortality in those cases in which it was administered in that manner but again there are no convincing figures to prove this point. It must be remembered however that it is almost impossible to evaluate these measures properly because as a general rule the series cannot be comparable. The patients with the most severe cases would be likely to receive antitoxin in large quantities by every route possible as soon as symptoms appeared and they in turn might show a high mortality while those with mild cases for whom serum treatment was postponed and was given in relatively small doses might show a high incidence of recovery. With the present limitation of knowledge with regard to the mode of action and the impossibility of estimating the amount of toxin already elaborated in any given case it seems best to lay down the following rules for the administration of antitoxin.

As soon as the diagnosis is made 20 000 USP units should be given intravenously 10 000 units into the muscles of the neigh-

borhood of the wound if possible and 10 000 units intrathecally after the removal of an equal amount of cerebrospinal fluid. The intravenous and intramuscular doses should then be repeated every four hours and the intraspinal injection every twenty-four hours until the outcome has been definitely settled. Some advocate the administration of as much as 500 000 units in the first twenty-four hours subsequent amounts being determined by the response of the patient to the treatment.

Symptoms.—Measures must be taken to combat the distressing effects of the muscular contractions which recur often with increasing frequency during the progress of the disease. Attacks are often brought on by various forms of afferent stimuli which should be minimized. The patient should be kept in a darkened room removed from all avoidable noises. The bed should not be jarred and the patient should be handled gently. If the contractures become violent frequent or painful the patient should be kept under the influence of sedatives which also serve to minimize his apprehension. The milder forms of sedation with the barbituric acid derivatives may not be sufficient but sodium amytal is the best of these and may prove sufficient for the milder spasm. Morphine which has the deleterious effect of repressing respiration should not be used. By far the safest sedative is veronal with which the patient may be kept continuously subdued for many hours but the dose should be limited to from 60 to 80 mg per kilo of body weight for larger doses may depress the respiration. Under its influence the muscles may completely lose their hypertonicity although this is not always possible. The return of spasm within the muscles even before the patient has shown evidence of coming out of the narcosis is an indication for its readministration. If spasticity of the respiratory muscles or action of the toxin on the center of respiration becomes manifest artificial respiration is necessary and can best be accomplished with the Drinker respirator.¹¹ When a prolonged narcotic is administered the danger of the development of pneumonia becomes great particularly when aeration of the lungs is limited by spasm of the respiratory muscles. Feeding the patient dur-

ing the period of prolonged narcosis must be handled with greatest care and elimination must be effected by rectal treatment. Improvement in the patient's condition is evidenced by an increase of the interval between the spasmodic seizures and a gradual relaxation of the contracture and hypertonicity of the muscles. The administration of narcotics can then be interrupted and gradually eliminated.

The high mortality of this disease after the development of symptoms should not lessen but should rather increase prompt and effective administration of all the aforementioned methods of treatment and these methods should be continued until the patient is completely out of danger or has succumbed. In many cases initial improvement has caused the surgeon to be unduly optimistic of the outcome or on the other hand the continuation of symptoms has led him to be unduly pessimistic. More careful study of the pathogenesis of the disease is essential before there can be hope for further lowering of the mortality rate.

RABIES

(Hydrophobia Lyssa)

Rabies is an acute infectious disease of dogs, horses, cattle, squirrels and other lower animals due to a filtrable virus found in the saliva. It is transmitted by a bite and is invariably fatal in human beings. In Illinois in 1936 18 466 dog bites were reported with 10 deaths from rabies. Cornell says that only 35 per cent of human beings bitten by rabid dogs die of rabies. The neurotropic virus passes along the nerve axons, cylinders from the site of inoculation to the central nervous system. At autopsy the brain shows the presence of specific Negri inclusion bodies.

The incubation period is shorter when the distance from the bite to the brain is less, varying from two weeks to over a year but is usually forty to sixty days. In a typical human case there is a short period of restlessness, apprehension and malice which is followed by the excitement stage in which there is a violent spasm of the muscles of swallowing and respiration. Attempts to swallow bring on an attack and the patient will refuse even water in circumstances which caused the disease to be termed hydrophobia. Saliva drips from the mouth owing to the patient's inability to swallow. The final stage is characterized by paralysis.

The high mortality of rabies (100 per cent) makes the treatment of animal bites of great importance. If it is known with certainty what animal caused the injury and

if this animal shows no signs of rabies the wound should be scrupulously cleansed with soap and water debrided if necessary and if indicated closed. This treatment is permissible only if the animal can be kept under close observation for two to three weeks and examined by a competent veterinarian. If the animal has been bitten by another animal Rosenau believes it should be quarantined for six months. If the animal has rabies develops rabies shows suspicious symptoms or is unidentified the patient should be given 14 to 21 doses of intracutaneous vaccine. Public health authorities advise the cauterization of all parts of the wound including the skin edges with 'fuming' nitric acid in every case if the animal is rabid. Meticulous cleansing with soap and water is thought by some to be preferable to cauterization. Any person whose appar-

ently intact skin has been contaminated by the saliva of a rabid animal should receive the prophylactic injections. All animal bites should immediately be reported to local health and police officers.

III. ANTHRAX, FUNGUS INFECTIONS AND TULAREMIA

ANTHRAX

(*Malignant Pustule, Splenic Fever, Malignant Carbuncle, Pustule Maligne*)

Definition.—Anthrax is an acute infectious disease caused by the *Bacillus anthracis* and characterized by the rapid development of a carbuncle-like lesion associated with severe constitutional symptoms

Etiology.—The disease is largely one of herbivora, attacking cattle, hogs, sheep and goats. Zoologically and geographically it is one of the most widespread of all infectious diseases. Among humans it occurs most

the point of inoculation. At first the lesion may simulate an ordinary furuncular infection, but it rapidly becomes transformed into a bulla filled with blood and pus. The surrounding tissue is indurated and board-like, and the edema is pronounced. The bulla ruptures exposing a dark brown eschar situated on a markedly inflammatory base, about the borders of which are seen minute translucent vesicles. The neighboring lymph glands are enlarged and may suppurate.

The lesion may occur on the face or neck if the infection has been the result of using an infected shaving brush and on the shoulder, arm or hand if due to the handling of diseased hides or skins (Fig. 10). In some cases the attendant symptoms of headache, high temperature and delirium are marked, in others the temperature may be only slightly elevated and the constitutional symptoms mild. The course of the disease is short; the patient either dies as the result of septicemia or recovers as the result of proper treatment.

Diagnosis.—The finding of a brownish black eschar situated on an exposed surface of the body, surrounded and covered by small vesicles and placed in the center of an area of marked swelling in a person whose occupation exposes him to anthrax infection generally suffices to establish the diagnosis. Anthrax bacilli are usually found in the smears.

Treatment.—At one time early and radical excision of the lesion was advocated. Best results now are obtained by leaving the lesion alone. Incision, excision or injections of chemicals or serum into or around the lesion is definitely contraindicated.

In a recent report Herman Gold reviewed his results in the treatment of sixty patients. Antianthrax serum was administered to twenty-one of the patients, twenty of whom recovered. The one who died had received an inadequate amount of serum intravenously and had been given injections of serum around the lesion. The average total dose of serum was 875 cc. administered in most cases in two or three intravenous in-

Fig 10—Anthrax

frequently among those who handle hides, hairs, bristles, wool, horn and bone and among farm laborers, shepherds, butchers and veterinarians. Shortly after World War I a number of cases of anthrax occurred as a result of infection from cheap pony-hair shaving brushes. *Bacillus anthracis* was the first organism discovered to bear a specific relationship to an infectious disease. It occurs as a large, straight, rod-like bacillus from 4.5 to 10 μ long and from 1 to 3 μ wide. It may occur singly or in pairs in film preparations. Its ability to form spores makes it extremely resistant to chemical and physical agents. The disease gains entrance to the human host by direct inoculation of the skin, seldom by ingestion or inhalation.

Symptoms.—A few hours or a few days after infection an inflammatory papule, accompanied by severe itching, develops at

jections. The initial dose should be 200 to 500 cc repeated every twelve to twenty-four hours until the edema is checked. Control of the edema is the most reliable means of determining whether sufficient serum has been administered. In addition to serum intravenous injections of nearsphenamine were given to six patients but this drug did not shorten the course of the disease or materially add to the chances of recovery. Sulfonamides were used in forty-two cases with excellent results in thirty-nine. Patients should be treated intensively with sulfapyridine and sulfathiazole but if they fail to respond after three days intrathoracic serum should be used. Sulfathiazole is the drug of choice. Gold believes that the illness was definitely shortened in his cases by the use of sulfonamides and that the sulfonamides are a safe and reliable substitute for serum and should be given preference in the treatment of anthrax.

SPOROTRICHOSIS

Definition.—Sporotrichosis is an infectious disease caused by a specific fungus, the *Sporothrix schenckii*, and characterized by the development in the skin of indolent nodules and abscesses. The disease may be localized or systemic; cutaneous subcutaneous, osseous and visceral lesions may be present simultaneously.

Etiology.—Farmers, gardeners and florists are especially affected and the disease occurs so frequently in rural districts that it suggests most strongly that the favorite habitat of the fungus is grasses, shrubs and other vegetable matter. More cases have been reported from France and from the Mississippi River basin than anywhere else. The sporothrix is strictly aerobic; it grows on ordinary media but especially well on those containing sugar.

Diagnosis.—The diagnosis of sporotrichosis is made by the cultivation of the organism on suitable media or by its inoculation into animals. It is difficult to isolate the organism from pus in suspected cases.

Pathology.—In sporotrichosis the pathologic picture is that of a chronic granuloma. The fungus can but rarely be demonstrated. All observers agree that three zones make up the granuloma: a peripheral zone where there is an intense inflammatory reaction of the connective tissue and the infiltrate is made up of plasma cells, lymphocytes and some connective tissue cells; a midzone in which are found numerous giant cells of the Langhans type and epithelial cells arranged in typical tubercle formation with a central zone in which are seen large numbers of pus cells lying in a fine or coarse connective tissue network.

Symptoms.—More than six clinical varieties of this disease have been described. The most important, however, are the localized lymphangitic and the multiple gummatous types. The disease is seldom recognized early. In fifty-one of 145 reported cases the disease had existed for four months before suitable treatment was instituted. Although it is usually characterized by the extreme indolence of its development and course and by an absence of fever and systemic symptoms, its onset may be abrupt with fever, symptoms of an acute septicæmia and a rapid development of lesions.

The first or lymphangitic type is the one most commonly seen in this country. A wound on the finger, thumb, forearm or hand serves as the portal of entry for the sporothrix. The initial lesion may simulate a simple ulcer, a furuncular pustule or an abscess. In some cases it may have almost entirely disappeared by the time that the succeeding symptoms develop. From a week to a month after the appearance of the initial lesion a chain of nodular swellings develops which follows the course of the lymphatics. The nodules slowly enlarge; some remain as painless nodular swellings, some soften with the formation of cold abscesses while in others the skin over them breaks down and indolent gummatous ulcers result. The chief lymphatic vessel extending from the initial sore can generally be felt as a thickened cord-like structure.

A second type not often seen in this country but often seen in France is characterized by the development of numerous lesions distributed over the trunk and limbs. They begin as nodules the size of a pea and enlarge slowly to lesions the size of a walnut. They only occasionally break down to form syphuloid ulcers. Generally they soften and form cold abscesses.

In the cases that have occurred in this country the lesions have broken down to form three types of ulcers: a tuberculoid ulcer which is fistulous in character with narrow irregular openings scanty pus and a dirty granulating base that bleeds easily; a syphuloid ulcer in which the lesions are crateriform clean cut with sharp edges; and an ecchymatous ulcer in which the lesions are superficial heavily crust covered and only moderately inflamed.

In addition to the skin the disease may attack the muscles, bones and mucous membranes especially those in the larynx and pharynx. Sporotrichal guinias have been found beneath the periosteum and cases of tibial periostitis due to the sporothrix have been reported.

Treatment—Surgical treatment is not indicated in sporotrichosis. Incision into the lesions increases growth rather than promoting involution. Potassium iodide by mouth in fairly large doses is almost a specific. Sodium iodide administered intravenously has also been of service in clearing up the disease.

ACTINOMYCOSIS

Definition—Actinomycosis is a disease affecting man, cattle and swine and characterized by the development of granulomatous tumors. These tumors fistulize and from their discharge the characteristic velvety sulfur like granules may be obtained.

Etiology—Considerable confusion has hedged about the origins of actinomycosis in man. The general assumption has been that the disease is conveyed to man in the following manner: A cow with lumpy jaw (actinomycosis) and a discharging sinus grazes at pasture; other cattle or human beings chew the grass upon which the actinomycetes were discharged and the disease is perpetuated. The present view and one that has gained adherents among both clinicians and bacteriologists is that actinomycetes frequently are harbored about the teeth and in the crypts of the tonsils and granted lodgment of the organism in a mucosal wound of the alimentary canal the disease process may be set in motion. Lord championed this view as long ago as 1910. The barrier to more general acceptance of the endogenous mode of origin of actinomycosis in man was that the cultural and morphologic characters of actinomycetes recovered from the oral cavities of patients with actinomycosis appeared to differ from the cultural and morphologic characters of the *Actinomyces bovis*. The latter organism was isolated from exudate by Harz in 1877 and its anaerobic character was established by Wolff and Israel in 1891. Emmons' obtained pure cultures of microaerophilic species of actinomycetes from carious teeth and from tonsillar crypts. Upon repeated subculture these actinomycetes and their hyphae behaved morphologically and culturally very much the same as did *Actinomyces bovis*. Emmons examined 100 pairs of tonsils removed by tonsillectomy and in forty seven found actinomycetes whose filaments exhibited the identical morphologic and staining reactions of *Actinomyces bovis*.

The clubbed ends of the twisted mycelial filaments together with their radial arrangement accounts for the fact that the actinomycetes colony is known as the ray fungus. The organism is gram positive.

Pathology—Lodgment of the ray fungus *Actinomyces bovis* in tissue brings about a granulomatous type of reaction in which the features of an acute as well as a chronic infection may be concurrently noted. Immediately about the organism a zone of cellular activity usually occurs in which are large masses of polymorphonuclear and mononuclear leukocytes and epithelioid cells.

and a rich network of young blood vessels. This reaction becomes manifest to the unaided eye as abscess formation with burrowing pus channels filled with purulent collections containing the yellow sulfur like granules of the actinomycetes colonies. The vascularity of this granulomatous process is always striking at operation. Hemorrhage from this tissue when curetted away may be alarming lending the impression that a large blood vessel has been opened yet slight gentle pressure with a gauze pack usually serves to arrest it. The yellow color of the exudate is due in large part to the presence of pseudanthrax cells rich in lipoids. The actinomycetes are non mobile but are carried into the surrounding tissues by macrophages.

Peripheral to this area of necrosis and liquefaction is observed a proliferation of dense connective tissue—an attempt to localize and stop the destructive process. The brown induration observed clinically in cases of actinomycosis is afforded by this keloid like proliferation of connective tissue. Central softening and peripheral induration with the suggestion of remarkable vascularity as imparted by the color of the skin are the gross features of the actinomycotic process which is about to rupture through the skin. Spontaneous fistulization with discharge of yellowish exudate is not unusual. In man primary involvement of bone is infrequent and is usually observed as an extension from an adjacent process in cattle involvement of the jaw bone is the most frequent initial lesion of true actinomycosis.

Sites Where Actinomycosis May Occur—There are essentially three regions in the body where actinomycosis commonly occurs viz (1) the head and neck (2) the thorax and (3) the abdomen. The usual portal of entry for cervicofacial actinomycosis is believed to be the mouth for thoracic actinomycosis aspirated or ingested organisms lodge in pulmonary tissue or penetrate the esophagus the usual lodgment of organisms which give rise to abdominal actinomycosis is the ileocecal segment of the intestinal canal.

The Spread of Actinomycosis—When the disease is recognizable clinically the portal of entry ordinarily remains but a conjecture.

The proximity of the disease process to one of the commonly accepted sites of origin of the disease merely suggests it as the portal through which the infection invaded the adjacent structures. Actinomycosis exhibits an extraordinary ability to extend into healthy tissue leaving no trace of the disease at the site of entry. This is particularly true of abdominal actinomycosis. It is likely that isolated actinomycosis in a subphrenic abscess the kidney the urinary bladder the female generative organs or the abdominal wall or a collection of actinomycotic exudate eroding the lower thoracic or lumbar spine commonly may have its origin in actinomycosis which initially found lodgment in the cecum.

Actinomycosis rarely becomes generalized in the sense in which a tumor metastasizes though instances apparently have occurred to indicate that distal spread by the blood stream does take place. Most of these cases concern the invasion of a pulmonary vein by an actinomycotic process in the lung its entry into the left heart and its propagation as a thrombus into one of the cerebral vessels with lodgment in the brain. Jacoby (1928) reviewed a number of these instances. Cerebral actinomycotic abscesses are sometimes multiple. Similar but less frequent spread to the liver spleen or kidney has also been noted. It is particularly the thoracic and abdominal varieties of actinomycosis which give rise to blood stream invasion. Because of the remarkable invasive features of actinomycosis by which the disease spreads by direct extension involvement of the liver and spleen may occur in either abdominal or thoracic actinomycosis by direct migration without the agency of blood stream metastasis.

In a fairly large number of cases of isolated actinomycosis of the urinary bladder the female generative organs the kidney and even bone the origin remains uncertain. As was suggested above undoubtedly some of these may have their origin in so called abdominal actinomycosis presumably being the residuum of an actinomycotic process which migrated out from the intestinal canal. It is possible that actinomycosis reached these organs by direct spread from an actinomycotic focus which had its origin elsewhere than in the intestinal canal. The

instances of isolated actinomycosis of the stomach which have been observed undoubtedly have their origin in the ingestion and direct lodgment of actinomycetes in the stomach.

Extension from cervicofacial actinomycosis may occur into the thorax by way of the supraclavicular fossa, and invasion of the cranium may occur through the orbit, by way of the foramina at the base of the skull or by direct erosion of bone. The importance of early recognition and adequate treatment of the lesion to obviate these unfortunate occurrences is immediately apparent.

obtained from a sinus or recovered by curettage at operation is put out on gauze or placed in water, where the granules may be identified more readily. Suspicious-looking granules are placed on a glass slide in a drop of strong potassium hydroxide, and this wet preparation is examined immediately. The sulfur-like granule of an actinomycotic colony is shown in Fig. 11, A. A coiled group of intertwined mycelial threads terminating in clubs is the typical picture. When fistulization has already occurred and drainage of exudate is slight, curettage of the sinus followed by paraffin embedding and staining with hematoxylin and eosin

Fig. 11—A, Sulfur granule (Gram's stain, $\times 250$), this is the typical ray fungus rosette. The conformation of the twisted mycelial threads is shown B, a number of actinomycete colonies surrounded by leukocytes. The organism is gram positive C, Gram's stain of a sulfur granule, showing the intertwining mycelial threads of the streptothrix ($\times 250$).*

Diagnosis.—That actinomycosis of the thorax or abdomen may not be identified early is obvious, why actinomycosis of the cheek or neck should not be recognized early is difficult to understand. A lesion which may be seen and palpated should suggest invoking aids to affirm or deny the presence of actinomycosis. Mere consideration of the possibility of the lesion goes a long way toward its identification if every lead is pursued to its logical conclusion.

The determination of the actual presence of actinomycosis rests upon bacteriologic means. The exudate recovered from an area of softening by needle aspiration or exudate

of a cut section will usually succeed in demonstrating the organisms when they cannot be identified in the exudate (Fig. 11, B and C). When sinuses have long been present in actinomycosis, the organisms may be difficult to find. They are most readily found in a lesion which has not been drained.

Differential Diagnosis.—*Cervicofacial Actinomycosis*—Patients may acquire the disease at any age, but the majority of patients are adults. Persons of middle age who have the disease usually are thought to have a malignant growth; in younger persons the

* Wangenstein: Ann Surg 104; J B Lippincott Co

most frequent diagnosis is tuberculosis of the lymph nodes. The trismus of the muscles of the jaw and the induration of the cheek and neck with discharging sinuses frequently suggest the picture of late intra-oral malignant disease. If the mouth can be opened adequately for examination the absence of an ulcerating lesion should at once give increased credence to the belief that the lesion is probably actinomycosis. Malignant disease, tuberculous lymph nodes or osteomyelitis of the jaw and suppuration in a branchial cyst may mimic the appearance of this variety of actinomycosis. The finding of the organism establishes the nature of the lesion.

Thoracic Actinomycosis.—Early recognition of the lesion is likely to be accidental. In my own experience it is the occurrence of an empyema which is threatening to rupture through the thorax in the vicinity of the breast or the anterior chest wall which gives the first indication of the presence of thoracic actinomycosis. Kirklin and Hefke (1931) have indicated that the roentgenologist may occasionally diagnose the lesion when the lung, pleura and chest wall are involved; that is, an intrapulmonary lesion which simultaneously gives rise to peritonitis should suggest actinomycosis. The clinician usually will suspect the presence of the lesion before the roentgenologist will be able to suggest the possibility of its presence from roentgenograms of the chest. Free bleeding following probing of a thoracic sinus tract may suggest the possibility of actinomycosis. Pulmonary abscess, bronchiectasis with abscess or crumification of the lung, tuberculosis, malignant disease of the lung or pleura, pyogenic empyema, unresolved pneumonia, syphilis of the lung, blastomycosis and hydatid cyst may give rise to confusion.

Abdominal Actinomycosis.—In most instances patients with abdominal actinomycosis are operated upon for appendicitis. Exudate may be found around the appendix, the true nature of the lesion remaining wholly unsuspected. An intestinal fistula may form or an abscess may appear in the incision subsequent to complete healing. The late occurrence of a subhepatic, subdiaphragmatic or perirenal abscess necessitating drainage may be the means by which

the process is identified. Any sinus which develops spontaneously in the abdominal wall should be looked upon with suspicion. Carcinoma, particularly in the cecum, Hodgkin's disease, appendiceal abscess and its complications, tuberculosis of the bowel and peritoneum, so-called regional ileitis with abscess formation, perinephric abscess and chronic granulomas are the ordinary conditions with which abdominal actinomycosis may be confused. Shiota (1909) related that localized actinomycosis had been cured by appendectomy or intestinal resection. Cure after gastric resection in which actinomycosis was discovered histologically, has been reported in a few instances. Similar cures have attended drainage of a subdiaphragmatic or pelvic abscess, actinomycotic in nature, which in all likelihood had its origin in an ileocecal lesion. Like results have attended excision of an actinomycotic kidney, as well as excision of an abscess of the fallopian tubes or ovaries or a process in the uterus which was found to be actinomycotic.

Treatment.—Actinomycosis has been known as a disease entity affecting man for almost sixty years. During this time a large number of agents have been recommended and tried in combating the disease. Only three have enjoyed wide usage, viz., surgical treatment, potassium iodide and irradiation. Among other remedies less frequently employed the following may be enumerated: vaccine therapy, methylene blue, copper sulfate, nearsphenamine, thiomol and injections of foreign protein.

Roentgen therapy of actinomycosis first employed by Harshtn (1901) of Chicago did not gain many adherents until after Levy of Breslau again advised its use (1913). Its endorsement by New and Figg (1923) and Heverdhil (1927) of Oslo have led to its wide employment in the treatment of this condition. That the method has virtue is attested to adequately in the numerous papers extolling the remedial properties of this therapeutic agent. The manner in which it operates is not clear. Kleesattel and Ingber (1928) have both indicated that roentgen ray or radium has no effect upon the organism. One cannot read the papers of Heverdhil (1927) and Engelstad (1932) and escape the impression that irradiation

has real merit. Roentgen therapy probably promotes fistulization and thereby accelerates healing.

The employment of potassium iodide in the treatment of human actinomycosis originated from veterinary medicine (1892). Veterinarians since have learned that potassium iodide is of no value in the treatment of *Actinomyces bovis*. In actinobacillosis, a disease of cattle and swine which mimics the pathologic aspects of true actinomycosis, however, potassium iodide acts as a specific terminating the disease. Actinobacillosis in man, on the contrary, has only rarely been observed. That the administra-

tion of the debris of the dead tissue which the diseased process brings about in which the oxygen tension is zero, the organisms thrive and are carried off by the macrophages into the healthy tissue in their attempt to combat the disease. Here again new abscesses develop with death of more tissue and the establishment of new areas of low oxygen tension which constitute favorable culture media for the perpetuation of the disease. What is obviously needed is excision of these areas of dead and dying tissue which propagate the disease. Surgical treatment has been the mainstay in dealing with actinomycosis in our clinic for fifteen years.

Fig. 12—Actinomycosis in a girl aged 13. After two curettements complete healing resulted.*

cure are on record particularly of abdominal actinomycosis. More recently, the sulfonamides have been employed with some success in complicated forms of the disease. Sulfanilamide and sulfadiazine appear to have particular merit. DeBakey² reports that penicillin too is of real value in actinomycosis. In all abdominal or thoracic forms of the disease, therefore sulfonamides and penicillin should be employed in addition to surgical evacuation of dead tissue.

BLASTOMYCOSIS

(*Blastomycetic Dermatitis Saccharomyces Hominis Dermatitis Blastomycotica Hefenmykose*)

Definition.—Blastomycosis may be either cutaneous or systemic. Cutaneous blastomycosis is a chronic inflammatory infectious skin disease characterized by the development of papulopustular lesions which extend peripherally and form variously sized elevated verrucous patches with sloping borders.

Etiology.—In most cases there has been a history of preceding trauma. Presumably infection occurs only after an injury. The majority of cases occur in men. There is, however, no relationship between the disease and sex. Fifty per cent of the cases

occur after the age of forty; the remainder between the ages of twenty and forty. It has been observed in younger and older patients. The disease is uncommon except in the neighborhood of Chicago. Most of the cases have developed without any history of association with other cases. Guinea pigs and rabbits have been successfully inoculated with the organism. The causative organism is a blastomycete or yeast, a species of fungus which multiplies by a process of cell division called budding. It is a round, oval or irregularly shaped body from 7 to 20 μ in diameter with a well defined double contoured capsule and a fine or coarsely granular protoplasm separated from the capsule by a clear space of varying width. To isolate the organism in a suspected case a small abscess situated in the sloping border of the lesion, not from the verrucous center, is punctured with a platinum pointed needle and a small amount of pus from it is smeared on a glass slide. To this is then added a few drops of a 25 to 40 per cent solution of potassium hydroxide. A cover glass is placed on top and the slide allowed to stand for a few minutes. It is then examined with the high power of the microscope and the diagnosis is made on finding the organism, preferably in budding forms.

Histopathology.—Histologically the lesions resemble those of verrucous tuberculosis and superficial epithelioma. The epidermis is throughout the seat of marked hyperplasia. The acanthosis is similar to that seen in the histology of venereal warts. The prickle cell layer is markedly edematous; the interepithelial lymphatic spaces are dilated and polymorphonuclear leukocytes in various forms can be detected between the cells. In the epidermis, milium abscesses are present which contain polymorphonuclear leukocytes, eosinophils, epidermal debris and usually several blastomycetes arranged singly, in pairs and in budding formation. In the corium there is a diffuse cellular infiltration occupying the upper layers, consisting of plasma cells, connective tissue cells, polymorphonuclear leukocytes, lymphocytes and a few giant cells. The collagen and elastin have lost their definition; they stain feebly and where the infiltration is densest they may have completely disap-

peared. The blastomycetes are found in milk-
ary abscesses between the epithelial cells and
in the corium rarely within the cells. Giant
cells usually contain one or more organisms.

Symptoms—The disease begins most
often following an injury even a trifling
one as a papule or papulopustule which
slowly enlarges peripherally to form a wart-
like papule and this in turn enlarges to
become a verrucous patch definitely ele-
vated from $\frac{1}{8}$ to $\frac{3}{8}$ inch above the skin.
A typical patch is generally bluish red and

cessible to the face hands wrists forearms
and eyelids. In the average case there may
be several lesions but in many cases there
may be a large number. The course of the
disease is chronic. Although patches may
apparently begin to heal even without
treatment some areas are very refractory
and recurrences are common even under the
most intensive therapy.

Systemic blastomycosis is that type of the
disease which affects the internal organs
principally the lungs liver, kidneys and
spleen and also the bones.

The chief symptoms are an irregular fever
(103° F) loss of appetite emaciation and
general weakness. In this type of disease
the cutaneous manifestations differ from
those seen in cutaneous blastomycosis. Sub-
cutaneous nodules and abscesses which later
develop into ulcers are commonly seen and
bony abscesses occur with complete destruc-
tion of the involved bone. In these cases
the pus from the abscess cavities discloses
the organism.

Diagnosis—The diagnosis of cutaneous
blastomycosis is made on finding budding
yeastlike organisms in the small abscesses
on the edges of the lesion.

Treatment—The treatment of blastomy-
cosis is principally medicinal. The best re-
sults have been obtained by the adminis-
tration of potassium iodide in large doses.
The patient is given a saturated solution
of the drug and instructed to begin treat-
ment with 10 drops well diluted in water
three times a day and to increase the dose
by 1 drop at every dose until involution
of the lesion begins. That dose is then
maintained. In resistant cases injections of
napharsen or neocarsphenamine at the same
time seem to be of considerable benefit in
enhancing the activity of the iodide. When
this therapy is resisted surgical excision of
individual patches can safely be done. Elec-
trocoagulation and excision with the cutting
current have also been used successfully.

Wet dressings of a 1 per cent copper sul-
fate solution are one of the best forms of
topical medication. Tincture of iodine and
saturated solution of gentian violet have
also proved to be of value as topical appli-
cations.

The disease is very stubborn but begins
to respond quickly to iodide therapy. It is

Fig. 13—Blastomycosis

covered by a bulky and adherent crust the
removal of which shows a surface distinctly
verrucous covered with papilliform eleva-
tions bathed in pus. The sloping borders
vary in width from $\frac{1}{4}$ to $\frac{3}{8}$ inch and on
close inspection can be seen to be the seat
of minute abscesses in which the organism
is found. The average patch in several
months may attain the size of a silver half
dollar (Fig. 13). It may often remain in-
dolent for some time but sooner or later it
will start to spread. In the course of sev-
eral weeks or months new plaques will form
in the neighborhood of the old one which
fact strongly suggests the possibility of
autoinoculation. Another point in favor of
autoinoculation is the location of the regions
most commonly involved those most re-

imperative to continue treatment until all signs of the disease have disappeared. Treatment in the systemic cases has so far proved of little value, and the prognosis is very grave. The mortality rate in that type of the disease is 90 per cent.

COCCIDIOIDAL GRANULOMA

(*Coccidioidomycosis*)

Definition.—Coccidioidal granuloma is an acute or chronic infection caused by a specific fungus. Most of the examples of the disease are observed in the San Joaquin Valley of California. A mild form of the infection is seen in the endemic area, the patients recovering without complications. Subcutaneous abscesses, verrucous skin lesions and meningel, respiratory, osseous or other involvement may be observed in chronic cases.

Etiology.—The causative fungus is *Coccidioides immitis*, which has a double life cycle. The *parasitic stage* is seen only in the host, where the fungus reproduces by endosporulation. The organism appears as a round, highly refractile, double-contoured capsule with an average diameter of 30 microns. Reproduction is by endogenous sporulation only. When the spores are mature, the wall of the capsule ruptures, and the spores escape to continue the cycle. Absence of budding differentiates it from blastomycosis. The *vegetative cycle* develops on all kinds of culture mediums as a white cottony growth. Arthrospores and chlamydospores only are formed in culture. The mold has been isolated from the soil in endemic areas. Infection is not possible in the absence of chlamydospores. In the dry season this fungus is blown about in the dust and inhaled by man. If local infections do occur, they are very unusual. The introduction of the

spores by trauma from contaminated thorns or twigs may produce local disease. It is pathogenic to cattle, sheep, guinea pigs,

Fig. 14—Coccidioidal granuloma. Subcutaneous abscesses on forehead and at sternoclavicular juncture.

Fig. 15—Coccidioidal granuloma. Verrucous type which clinically resembles blastomycosis.

monkeys and man. Man to man or animal to man transmission has not been observed.

Histopathology.—The *Coccidioides immitis* organism has been shown to invade every organ in the human body except the intestinal tract. It creates a pathologic pic-

ture similar to that seen in tuberculosis the lesions in coccidioidomycosis showing a greater tendency to suppuration than the lesions of tuberculosis. Cutaneous involvement is in the deep cutis and is generally secondary to a systemic infection.

The characteristic lesions have a tubercle-like formation with some central necrosis and giant cell formation. The surrounding infiltrate consists of lymphocytes, plasma and epithelioid cells. The organism may be found in the giant cells or scattered throughout the cellular infiltrate. A positive histo-

disease may be the result of a recently acquired infection or a late manifestation of an infection acquired in childhood. In this and many other respects the disease closely resembles tuberculosis.

The early cutaneous lesions of coccidioidomycosis are often observed on the exposed parts of the body. Subcutaneous abscesses, verrucous lesions, granulomatous nodules or indolent ulcers being observed on the skin. Destruction of bone, lymph node involvement and meningeal manifestation are less frequently found. Pain is not a prominent

Fig. 16.—Mature double-contoured organism of coccidioid granuloma in tissue.

pathologic diagnosis cannot be made unless the double-contoured endosporulating organism is found.

Clinical Manifestations.—An infection with *C. immitis* may manifest itself in various ways. A primary acute infection of the respiratory tract sometimes associated with erythema nodosum has been recently described under the name of San Joaquin Valley fever. This type of involvement is more prevalent among children and new residents of the endemic area and presents a definite problem for the military forces stationed in the San Joaquin Valley. There is a fulminating type of respiratory involvement generally observed in adults which may terminate fatally in six to eight weeks. Most examples of this form of the disease are seen in new inhabitants of the endemic area. The subacute or chronic granulomatous form of the

symptom except in cases of bone or meningeal involvement.

There is usually low grade fever in these cases with moderate leukocytosis the count being 10 000 to 15 000.

Diagnosis.—Coccidioidal granuloma must be differentiated from tuberculosis, syphilis, cancer, blastomycosis and the other deep mycoses. The clinical and pathologic manifestations of coccidioidal granuloma, tuberculosis and blastomycosis are so similar that a differential diagnosis can be made only by laboratory methods. Pus, sputum, bone scrapings, spinal fluid or tissue may be examined. The double-contoured endosporulating organism must be demonstrated in pus or tissue or in laboratory animals. The final diagnosis rests upon the demonstration of both the parasitic and the vegetative cycle.

The *coccidioidin* test is analogous to the tuberculin test. Its specificity is generally accepted by most investigators. However a diagnosis should never be made on this test alone but the results may be of considerable value as confirmatory evidence. Complement fixation and precipitation tests are aids in diagnosis and prognosis. It has been shown that 69 per cent of a group of children over fifteen years of age in the endemic area reacted positively to the test.

Prognosis—Most of the patients with primary acute coccidioidal infection of the respiratory tract recover spontaneously in four to six weeks. In the granulomatous type of the disease the mortality is approximately 50 per cent.

Treatment—The general treatment in cases of chronic or acute fulminating coccidioidal granuloma should be the same as for tuberculosis. Rest, sunshine and good food will generally accomplish more than other measures. Many drugs have been used but only antimony and potassium tartrate, thymol and colloidal copper seem to have given some therapeutic results. Sulfa drugs and other related products have not been found to be of value. Vaccines have been reported to be of use in some cases and roentgen therapy has been effective in a few instances.

Abscesses may be incised and drained. A few cases have been reported in which amputation of an infected extremity has cured the disease. Most patients have a systemic infection and surgical treatment or other local therapy is only palliative.

In endemic areas patients with mild systemic infections generally recover without treatment.

TULAREMIA

Synonyms—Francis disease, deer fly fever, rabbit fever, Olans disease, wild rab-

bit disease, the first American disease, plague like disease of rodents, glandular type of tick fever and alkali disease.

Definition—Tularemia is an infectious disease caused by *Bacterium tularense*.

Etiology—*Bact. tularense* first isolated in 1911 by McCoy and Chapin from ground squirrels (*Citellus beecheyi*) dead or dying from a plague like epizootic in Tulare County, California, was named after the county in which the discovery was made. It is the cause of a fatal bacteremia of rodents, especially wild rabbits and hares. The infection is transmitted to man (1) by the bite of an infected blood sucking fly, the horse fly (*Chrysops discalis*) (Williston), commonly found on horses and cattle, which also bites rabbits and man; (2) by the bite of the wood tick (*Dermacentor andersoni*) (Stiles) by the bite of a tick (probably *D. variabilis*) or by contamination of the hands or conjunctival sac with the internal organs or body fluids of infected rodents, flies or ticks, and by the bites of animals. The name *tularemia* was given to the disease on account of the presence in the blood of the causative *Bact. tularense*.

Epidemiology—Human cases of the disease have been reported from the District of Columbia and all of the states of the Union and also from Norway, Sweden, Russia, Japan and England. According to a public health report (1910) there were in the United States 2,088 cases with 190 deaths during 1939. In 1940 there were 2,900 cases with 150 deaths (approximate returns incomplete). Wild rabbits and hares are the direct cause of more than 90 per cent of human cases in the United States. Horse flies have caused 68 cases in Utah and the surrounding states. Wood ticks have caused 53 cases in Montana and the surrounding states. Sheep contact has caused 12 cases in the Northwest. Insect bites (species undetermined) have caused 9 cases, tree squirrels 14 cases and opossums 9 cases. One case each followed skinning or dressing a sage hen, coyote, deer, red fox and bull snake. Two cases each followed like contact with quail, ground hog, muskrat, hog and skunk. Eleven were caused by scratches or bites from cats. Lard, insufficiently cooked rabbit meat caused 20 cases with 12 deaths. The disease shows marked seasonal varia-

tions in different parts of the United States. In the West the incidence corresponds with the time of the greatest activity of the wood ticks (March to August) and deer flies (June to September) and to the time jack rabbit hunting is greatest (spring, summer and early fall). East of the Mississippi the incidence is limited almost entirely to the open season for hunting wild cotton tail rabbits (November, December and January) (Simpson). The disease occurs chiefly in persons who skin and dress rabbits, hunters, market men and cooks. No abrasion of the skin is necessary as a portal of entry for the infection. All ages are susceptible. The age limits of reported cases range from two to seventy-three years. One attack is believed to confer lasting immunity. There is no evidence that the disease is contagious from man to man. No instance has been reported of the spread of the disease from man to man by mere contact or by an insect's biting a patient and then another person. Only one case is on record (Harris) in which the primary lesion developed in a skin abrasion in a person dressing an open ulcer of a patient with tularemia. One case is reported of a man who had his finger pecked by a chicken hawk which he shot while it was feeding on a dead rabbit. The man did not touch the rabbit.

Pathology—*In Man Acute Lesions*—1. A primary ulcer shows a diffuse necrosis with nuclear fragmentation and infiltration with polymorphonuclear leukocytes beyond which there is a zone of infiltration with small lymphocytes. 2. Affected lymph nodes show focal and diffuse necrosis. 3. The spleen shows on its surface and throughout its pulp necrotic foci bordered by normal splenic pulp. 4. The liver shows small necrotic foci. 5. The lung shows small necrotic foci on the pleural surface and cut sections show small areas of focal necrosis, bronchopneumonic patches or consolidation of almost an entire lobe (alveolar pneumonia).

Subacute Lesions—Subacute necrosis is characteristic of the lesions after the end of the second week. Histologically areas of focal necrosis show a central erosive zone surrounded by a zone of epithelioid cells and fibroblasts arranged radially and a peripheral zone of lymphocytes among which there

may be a few giant cells. The picture resembles that of tuberculosis.

In laboratory animals inoculated for diagnostic purposes death usually occurs within a week. Cessation of the enlarged lymph nodes and numerous discrete areas of focal necrosis are found studded over the enlarged spleen especially and over the liver. The lesions are often minute and for this reason the organs should be viewed in direct sunlight or under strong electric lights. It is also well to use a hand lens. The appearance is characteristic and is well described by the terms spotted spleen and spotted liver.

Symptoms—There are eight clinical types of the disease: (1) *Ulceroglandular*. A primary lesion, a painful red papule which later becomes a pustule; the center becomes necrotic and is liberated leaving a circumscribed punched-out ulcer with a reddened periphery. The ulcer is persistent and does not respond to treatment with antiseptic dressings, later breaking down to form an ulcer of the skin accompanied by enlargement of the regional lymph nodes, by far the most common type. (2) *Oculoglandular*. The primary lesion is conjunctivitis accompanied by enlargement of the regional lymph nodes. (3) *Glandular* without any primary lesion but with enlargement of regional lymph nodes. (4) *Typhoid or septicemic*, no primary lesion or enlargement of lymph nodes. (5) *Ingestive*. (6) *Pneumonic* (bronchial or lobar). (7) *Meningeal*. (8) *Anginal*. Fulminant cases rapidly fatal occur in types 1, 2, 3, 6 and 7.

Incubation—The incubation period varies from one to ten days, usually it is two, three or four days. The average period is about three and one-half days. The onset often occurs during sleep or while the patient is at work and is characterized by gripe-like symptoms.

Onset—A sudden onset is characteristic with severe headache, fever, chilliness or repeated chills, profuse sweating, rhegms in the back and extremities, marked prostration and sometimes vomiting and diarrhea. *Fever* is always present in cases of tularemia and shows a characteristic curve. The initial temperature ranges between 101° and 103° F. and as a rule is septic in character. It lasts one, two or three days followed by a fall and then a secondary rise to the org-

inal height after which it *gradually declines to normal* at the end of from two to three weeks. In the glandular types there is only a moderate increase in the pulse rate, as a rule to about 90 and practically no increase in the respiratory rate. The early remission of temperature is accompanied by the diminution of all symptoms and the patient often believes he is well but soon the symptoms return and there is a *secondary rise* of the temperature. There is *moderate leucocytosis* (possibly 16 000 leukocytes) but it is of no diagnostic importance. In some cases skin eruptions occur on the arms and neck on the trunk and on the abdomen they are maculopapular papular papulopustular, with a few vesicles and eventually scaling erythema multiforme like and scarlatiniform. The skin eruption in itself, does not aid in the diagnosis.

Most cases show a considerable degree of chronicity. Convalescence is slow and is characterized by fatigue. It may require six months to a year for the patient to regain his normal strength. Recovery is usually without sequelae. *Complications* are unusual.

Prognosis—The mortality rate is rather low in cases of tularemia ranging from 16 to 4 or 5 per cent in the United States. Symptoms and findings of pneumonia meningitis or peritonitis are bad prognostic signs. Once over the disease the patient is immune.

Diagnosis—The diagnosis is based on (1) the patient's history of having handled wild rabbits or having been bitten by a tick or fly, (2) a primary lesion of the skin beginning as a painful papule or pustule followed by a persistent ulcer or by a primary conjunctivitis followed often by ulcers of the conjunctiva, (3) persistent firm tender glandular enlargement at times quite painful in the regional lymph nodes and (4) fever of from two to three weeks' duration.

The diagnosis is confirmed (1) *earliest* by *Foshay's intradermal test*. An intradermal injection of a vaccine of a chemically detoxified dilute suspension of *Bact. tularensis* causes a local reaction—a simple erythema. The test is absolutely specific; it proves the presence of the disease if it is positive in all cases from the second day to the fifteenth month and it is especially useful during the first twelve days when agglutination tests are

usually negative. It has not been found to be positive in any other disease. The test becomes negative only when the disease is completely cured. (2) The *agglutination test* is useless during the first week or ten days but always becomes positive during the second week and the agglutinins reach the highest titer during the third week (Dickey). Thereafter it is highly specific and is the simplest and probably the best method of confirming the diagnosis. With the exception of an occasional cross agglutination of *Bact. tularensis* and the *Brucella* organisms the agglutination reaction for tularemia is highly specific. Agglutinins persist in the blood for many years (Dickey). (3) The diagnosis may be confirmed by *animal reproduction of the disease* with isolation of *Bact. tularensis* from guinea pigs rabbits or white mice inoculated with the blood of the patient during the first days or with material taken as early as the first week from the primary lesion or from the enlarged regional lymph nodes at the time of spontaneous or surgical drainage. It is seldom successful for weeks or more after the patient is infected. Pus from the patient's lesion (primary or suppurating lymph nodes) is rubbed in a mortar, suspended in salt solution filtered through coarse gauze and injected subcutaneously into the abdominal wall of a guinea pig or rabbit. Blood is defibrinated and mixed with an equal amount of normal saline solution and from 4 to 8 cc is injected intraperitoneally into the guinea pigs. Dickey states that the organism can be grown in mediums containing cystine but it grows very poorly or not at all in routine blood agar and brain broth.

Differential Diagnosis—The diseases which must be considered in making a differential diagnosis include climatic bubo resulting from a rat bite influenza pneumonitis typhoid fever, septic infection sporotrichosis undulant fever meningitis, peritonitis from other causes Parinaud's conjunctivitis and conjunctivitis necroticans infectious erythema multiforme malaria and tuberculosis. Dickey points out the importance of keeping the pneumonic type in mind when one realizes the frequency of pulmonary complications in tularemia. Although the seriousness of tularemic pneumonia is not to be denied the present tendency is to

consider it less fatal than previously recorded. Early treatment with an antiserum has helped produce this change in opinion. Any atypical pneumonia with a relatively low white blood cell count, a slow pulse rate and slow evolution of lung changes should cause one to suspect tularemia. This disease must also be considered in cases of pleurisy with effusion. A chest roentgenogram should be taken in every case of tularemia.

Prophylaxis is the most important phase of treatment. 1. Wild rabbit should always be thoroughly cooked so as to render any infected meat harmless for food. 2. Laboratory workers and all persons who handle wild rabbits should wear rubber gloves. Patients with tularemia do not require isolation or quarantine but persons who dress tularemia lesions should wear rubber gloves and should use ordinary disinfectants on their hands. 3. The most important recent advance is vaccine prophylaxis (Foshay et al.)—the administration to susceptible individuals of 3 doses of 0.5 ml each of a vaccine injected subcutaneously and alternately into the arms on either consecutive or alternate days completing the administration within a 6 day period to avoid sensitization reaction. A study of 2145 persons so vaccinated showed that definite protection was obtained and those who did acquire tularemia exhibited significant amelioration and shortening of the disease. Such protection lasts about one year, seldom longer, sometimes less. Consequently re-vaccination is advised at least annually when exposure is seasonal, every three or four months with small doses during the period of exposure where exposure is anticipated throughout a period of several months or longer. Prophylactic vaccination is best completed at least three weeks before the anticipated exposure but there need be no fear of inducing harmful effects by administering vaccine immediately prior to exposure or during the incubation period.

Treatment.—Confinement to bed is of utmost importance during the acute stage of the disease as long as the fever lasts. *The primary lesion should never be incised.* The enlarged lymph nodes should never be excised or even incised until suppuration is advanced until the mass definitely fluctuates and the skin overlying the mass is thin

and about to rupture spontaneously. Then only a very small incision is indicated. If the patient is seen early and properly treated suppuration of lymph nodes should not occur.

Early active treatment includes the use of *convalescent serum*, the patient receiving a transfusion of from 200 to 500 cc of blood from a compatible donor who has completely recovered from tularemia. This treatment appears to arrest the progress of the disease, but not enough experience has been accumulated to justify the making of definite conclusions.

A *specific antiserum* prepared from vaccinated goats has been developed and used by Foshay. The beneficial effects appear soon after its administration. Within twenty-four hours there is usually complete relief from headache and a marked diminution in the intensity of the general malaise, arthralgia and myalgia. The ulcers become less painful and healing is well under way before the end of a week. The temperature rapidly falls, the enlarged lymph nodes quickly diminish in size and if treatment has been early enough suppuration does not occur. The antiserum should be given as early as possible in order to prevent glandular suppuration and also death from the septicemia.

Serum therapy definitely shortens the duration of the primary lesion, fever, hospitalization, lymphadenopathy, disability and course of the disease. Unpreserved serum is far more potent than that containing any preservative. Two doses of 15 cc each given intravenously on successive days are far more effective than only one dose or than two doses administered subcutaneously or intramuscularly. In cases of the typhoid type or cases of the ulceroglandular type in which the enlarged nodes measure more than 5 cm in diameter the patient should be given daily doses for three or more successive days or perhaps larger amounts. Later workers have used 0 cc the first day and 90 cc the second day. Rohmiz warns that antitularemic serum frequently causes anaphylactic reactions, that the usual precautions should be taken to avoid reactions and that serum sickness does not always manifest itself by an urticarial or erythematous rash but swelling of lymph nodes, joint and muscle

pains, headache and fever may develop. These symptoms may be mistaken as indicating a relapse and more serum may be given, with disastrous results. He suggests that serum treatment be reserved for serious cases. When there is evidence of sepsis and visceral involvement, serum therapy may offer the only hope and larger doses should be given. The initial dose may be as high as 90 cc; this should be followed by injections of 30 cc every 8 to 12 hours until definite improvement is noted. Live anti-tularemia serum has been found to be effective and easy to administer (Flinn, Toman and Murr). Sulfu drugs have been used with varying success. Some observers among them Moss and Weilbaecher (1941) report rapid clinical improvement in several severe cases while others including Shaffer (1943) report lack of response. Loria reports the use of acriflavine with marked success in 3 cases. 100 mg of acriflavine dissolved in 250 cc of normal saline solution being administered every 72 hours for three or four treatments. However, he believes that further observations on the use of this drug in tularemia are necessary before its efficacy can be definitely evaluated. Josey reports the use of 1,900,000 Oxford units of penicillin intramuscularly in a case of pneumonic type tularemia without any beneficial effect.

IV. THERMAL, CHEMICAL, ELECTRICAL AND IRRADIATION INJURIES

THERMAL BURNS

Thermal burns have been a conspicuous cause of death in civilian disasters and modern warfare. They will remain a surgical problem as long as petroleum and illuminating gas are used for motive power and heating and as long as buildings are made of inflammable material.

World War II accompanied by an increased incidence of thermal burns has challenged the surgeon's mode of handling them and their complications—shock, infection and malnutrition and with the aid of materials such as plasma and chemotherapeutic agents, avowedly the mortality has been reduced. Up to 1941 it was conceded that a burn involving more than 50 per cent of the body surface would prove fatal. Now a patient with a burn of more than 70 per cent even if the greater proportion is full thickness is not doomed.

It would be fallacious to ascribe to the impetus of World War II the entire improvement in burn treatment for ever since World War I knowledge regarding the nature of burns had been accumulating. Progress in the therapy of burns has been thwarted by the surgeon's narrow habit of concentrating on the wound. A broader point of view emerged from the study of shock in World War I. Underhill and Davidson under this influence made the first contribution to the therapy of burn shock by pointing out the fluid and electrolyte deficiency. A decade later Block and Harkins measured the protein loss from the blood stream into the wound which controls fluid and electrolyte distribution. Elman introduced plasma transfusion. Finally Fier and Ahlrich conceived of the early influence of infection in burn shock.

The rationale of the treatment of burns is dependent upon what is known of their pathologic anatomy and physiology.

NATURE OF THE WOUND

The application of sufficient heat to a body surface to create a burn precipitates a

chain of events including pain, alterations in blood flow, increased capillary permeability, edema and increased lymph flow. To these physiologic changes is usually appended some degree of cell necrosis.

Pathologic Anatomy—It is essential for purposes of treatment to record the extent and the depth of the burn, necrosis and whether the epidermis is intact. Burns are classified according to the depth of the necrosis into three categories: first, second and third degree. (The Dupuytren classification with six categories is unnecessarily cumbersome.) The first degree burn is mild and of such superficial nature that blebs do not form. The burned area is indented by the dilated capillaries and edema of the skin. Visible necrosis may be absent but usually such a burn is followed by peeling of the superficial part of the epidermis. Healing originates in the germinating layer of the epidermis and is completed within a few days without a scar.

The term *second degree* denotes a burn with necrosis extending into the derma but with viable epithelial remnants; this wound will heal without grafting. By definition the necrosis involves the entire epidermis but varying depths of the derma. It is good practice to divide the category of second degree burns into superficial and deep. Superficial burns epithelialize rapidly from the numerous gland crypts and hair follicles near the surface even in the presence of an intact dead epidermis and bleb fluid. Healing without scarring is expected within two weeks. In the deep second degree burn there are fewer epithelial remnants for regeneration and the tough fibrous slough must be shed before the cells can blanket the surface. During the process of slough cleavage there may be considerable fibrous tissue proliferation. Healing is therefore tedious and there will be scarring.

Second degree burns are most easily detected by the blabbing which occurs. Blebs form in the deep epidermal layer or between epidermis and derma but not in the derma.

itself presumably because of the presence of abundant tough collagen in the fibrous stroma. Blebs enlarge as the pressure of edema fluid rises and are not seen immediately. Blebs do not form in the deep second degree burns where the heat coagulates the superficial layers of the wound. This is particularly true in the portions of the body where the skin is thick: the buttocks, upper thighs and lower back. In these areas the surface appearance of the wound may resemble that of a third degree burn.

Third degree or full thickness designates those burns in which the skin and all epithelial elements are destroyed. Epithelialization can start from the periphery or grafts only after the slough has been eliminated. Spontaneous elimination requires three to five weeks. Such wounds are disclosed by either a charred or blanched coagulation of the tissues which have no circulation. Blebbing is rare. They may be further identified by lack of local pain and sensation since presumably the sensory nerve endings in the skin have also been destroyed.

It is sometimes impossible to ascertain the depth of skin necrosis particularly immediately after the burn before the edema has completely formed. During the period of pain a superficial second degree burn may be white owing to arteriolar constriction and may resemble a third degree wound. Nothing better than the eye has been devised with which to distinguish the depths of skin necrosis.

The extent of the burn is best computed in the percentage of total body surface using the scale of Berkow as given in the accompanying table.

Flames and hot gases may burn the respiratory tract as low as the trachea and edema may produce laryngeal obstruction. The damage most to be feared in the respiratory tract is that to the bronchiolar epithelium caused by irritant gases from a configuration in an enclosed space. Bronchiolar spasm, edema and epithelial denudation may result in respiratory obstruction and death.

In burns about the face the eyes occasionally are damaged. Deep corneal necrosis is rare.

Pathologic Physiology.—Pain.—Acute pain is elicited in the sensory nerves of the

THE BERKOW* SCALE FOR ESTIMATING EXTENT OF BURNS

skin by heat but also in the damaged vascular bed if the intracapillary pressure is raised. Prompt relief is obtained by cooling, an effect produced in part by a decrease in blood flow.

Increased Blood Flow.—The blood flow to a burn and its immediate vicinity is augmented partly by direct trauma to the small vessels within the wound and partly perhaps by reflex dilatation of the vessels beneath the wound. (Initially there is transient blanching of the skin or decrease in flow, which may be prolonged for minutes by a pain reflex.) The increased flow is a component of the inflammation of the wound and persists until the wound is healed.

Increased Capillary Permeability.—The capillaries become more permeable in the burned area: a protein rich plasma filtrate pours out distending the interstitial spaces. The edema thus produced may involve not only the skin but also the more readily distensible subcutaneous tissue. The visible cutaneous edema therefore may not be a true indication of the volume of fluid which has

* Berkow, Ann. I. Surg. 32

escaped from the blood stream. Hence the extent of the burn rather than the depth, is a guide to the volume of the fluid lost.

The integrity of the capillary wall is not entirely destroyed in those capillaries of the wound in which the circulation is maintained and through which the edema fluid exudes. The edema fluid of burned patients has not been measured directly; what is known about it is derived from measurements on bleb fluid. It is assumed that bleb fluid is a close approximation to edema fluid since there is evidence of a constant interchange. Red blood cells do not escape from the capillaries and part of the protein, principally the globulin fraction, is retained. The average protein concentration of bleb fluid in the first two days after the burn is 4.0 Gm. per hundred cubic centimeters. The concentration fluctuates slightly with the severity of the burn and decreases as the burn wound heals. The concentration of fibrinogen and thrombin approximates that in the plasma, as does that of all the freely diffusible substances such as the non-protein nitrogen, carbohydrates and electrolytes.

Congulation of the edema fluid of the wound is negligible; this is verified by the prolonged weeping from a bleb with a broken roof. With the rise in edema and interstitial fluid pressure there is an increased return of the capillary filtrate through the lymphatic trunks to the blood stream. As fluid continues to pour out of the capillaries there is a slow flushing of the wound.

The retarded coagulation of the fluid of the burn wound permits free interchange of diffusible substances. Sulfonamides injected intravenously permeate the wound and those applied on an open area are rapidly absorbed.

The nature of the burn wound may be altered by infection and the superimposed infectious inflammation. As long as the corium of the skin is intact, even though killed by heat and lifted off the dermis as the roof of a bleb, organisms have difficulty in penetrating into the wound. Virulent organisms are usually not found in the fluid of unruptured blebs. When the corium is broken, either by the rupturing of a bleb or cracking by the heat, bacteria infiltrate the wound.

GENERAL CONSEQUENCES OF LOCAL CHANGES

Shock.—The generalized vasomotor collapse or primary shock, presumably of neurogenic origin associated with pain and excitement, is instantaneous, transitory and of little clinical importance. The shock which must be respected is that due to a diminishing circulating plasma volume which is caused by continuous seepage of plasma out through the damaged capillaries. As the plasma volume is reduced without concomitant loss of red blood cells, the hematocrit or red cell concentration and the viscosity of the blood rise. The blood flow is impeded, the cardiac output is curtailed, the blood pressure falls and there is an inadequate circulation to the unburned organs and tissues as well as to the wound. In an extensively burned patient advanced shock is present within an hour.

Because of its dilated arteriolar bed the wound is a parasite upon the failing circulation and steals blood from the vital organs. The circulation to the brain may be maintained until the last, but the kidney, liver, intestinal tract and muscles may be sentenced to live under anaerobic conditions. Circulation in the kidney may be so retarded that renal function is almost or entirely stopped. Excretory products accumulate. If the renal blood flow is cut off for a few hours the kidney cells may be so injured that they never recover, and even if the general circulation is restored death in uremia follows some days later. Functions of the liver, such as deamination and glycogen synthesis, are eliminated in the absence of adequate oxygen. The products of anaerobic muscle metabolism differ from the aerobic; the concentration of organic acids, such as lactic and pyruvic acid, rises and produces a generalized acidosis. The intestinal tract cannot serve anaerobically and it regurgitates fluid and food taken into the stomach. With the ensuing dehydration there are electrolyte changes as the result of a shift of intracellular water.

Infection.—Infection prospers if organisms gain entrance to the burn wound. Not only are the viable cells killed and wound healing retarded, but shock and malnutrition are fostered. Shock and infectionabet each other for if some degree of circulatory

failure is present many of the virulent organisms including strains of the streptococcus proliferate more rapidly under the partial anaerobic conditions. Malnutrition and anemia from red cell destruction may hobble the recovery of the deeply burned infected patient. Infection engenders fever and is the only known source of toxemia in burns.

Elimination of Abnormal Protein—Massive hemolysis, hemoglobinuria and albuminuria may be observed in severely burned patients within the first few days. The red cells are broken and rendered fragile by the intense heat. The source of the albumin in the urine is not established; it is believed that cell and plasma proteins are denatured by the heat and infection and when absorbed from the wound have to be excreted if not metabolized. If an adequate plasma volume and blood flow to the kidney is maintained, such albuminuria and hemolysis leave no permanent damage.

Alarm Reaction—The general physiologic response to trauma has been termed the alarm reaction by Selye. Burns as well as fractures and muscle trauma initiate a metabolic and glandular reorientation in which a rapid loss of non-protein nitrogen through the kidney overshadows other metabolic changes. The adrenal cortex is summoned to overactivity; this is demonstrated by an immediate rise in 17-ketosteroid excretion to a level above normal for a week. The metabolic disturbance may last until the wounds are healed and may be modified by an intercurrent infection and surgical procedures which reinstate the acute phase of the alarm reaction.

TREATMENT

The treatment of burns consists of the preservation of life, prevention of complications and the expeditious healing of the wound. The measures to apply are considered separately for the sake of clarity but they must be synchronized and the plan depends upon the exigencies.

Primary Surface Treatment—The treatment of the surface is reviewed first because it should be initiated the moment the patient is burned, not because it is the immediate life-saving measure.

At the moment the burn occurs the wound is essentially sterile. Contamination of this

wound should be discouraged by protecting it immediately with a sterile dressing. If this dressing is applied by a physician competent to judge the extent and depth of the burn, it constitutes the *primary surface treatment*, both first and definitive. If the initial treatment is carried out by a lay individual in the absence of the responsible physician, it is called *first aid treatment*, even though it is identical to that which would have been applied by the physician. Following the first aid treatment, the responsible physician will need to revise the dressing to determine the extent and nature of the wound and this is called *definitive treatment*.

Before the dressings are applied, the physician should be sure that an accurate chart of the extent and depth of the burns can be reconstructed. This is indispensable for the treatment of shock and subsequent care of the surface wounds.

There is no known substance which expedites healing of a wound beyond the rate obtained under normal physiologic conditions and in the absence of infection. The substance to be applied locally to a burn wound is one known to be non-injurious to tissues and an effective barrier to the invasion of bacteria. Gause, petrolatum, carbowax ointments and petroleum greases and oils are such substances. All of these can be sterilized. Petrolatum and gauze used in combination is the treatment of choice. Grease has the additional qualification of being soothing. Automotive greases or oil may be used if petrolatum is not available. Since they do not conform to pharmacopoeial standards, they are used only in emergencies. However, a compromise surface dressing if immediately applied is better than accepting bacterial contamination by awaiting a better one. The disadvantage of the carbowax ointments is that they are absorbed and leave an adherent uncomfortable dressing.

Tannic acid, gentian violet and the tripl dyes are known to be injurious to cells and are not recommended. Tannic acid is toxic and when absorbed causes liver damage.

Boric acid and various sulfonamides which can be incorporated in ointment bases are not injurious to cells except in high concentrations. However, they are absorbed

from the wound and their internal toxicity eliminates their use. Ointments containing either may be applied to burns of small extent. Since they should not be applied to extensive burns it is wise to exclude them.

Pressure bandages should be applied over the dressings of wounds of the face, scalp and extremities in order to diminish the volume of edema and immobilize the wound. By checking the edema less plasma is lost from the blood stream. Immobilization aids the body in localizing the infection. The pressure must be carefully applied in order to avoid a tourniquet effect. On the extremities it should always start at the toes or fingers and diminish proximally. Elastic bandages over thick sluffs, graze or mechanical waste achieve even pressure. Rolled newspapers may be incorporated as splints. The extremities should be fixed in the position of function. The dressings of the head and scalp may incorporate the chin but not the neck. Plaster bandages are the ultimate in pressure but to be effective must be applied immediately after the burn before any edema has collected. They are useful only for the extremities; even then application is difficult over fingers and toes and a tourniquet effect is easily produced. The lack of time and personnel precludes their use in a catastrophe.

The primary dressing is applied with no cleansing or debriding of the wounds. If the wounds have been grossly contaminated with manure or dirt they should be generously irrigated with running water. It is impossible to rid a wound of all bacteria without excising it or applying corrosive chemicals. The debridement of superficial burns which consists of removing epidermis that over intact blebs or that rolled up in the corners of ruptured blebs only violates the protective barrier and serves no purpose. It is a relief of the tannic acid method. Debridement of deep burns is a major operative procedure and must be postponed until shock has been combated and the patient is ready for skin grafting.

A primary dressing of petrolatum gauze and pressure is suitable for burn wounds no matter what the circumstances. It is so simple to apply that in a disaster where there is a disproportion of casualties to trained medical personnel the latter can be

freed for the more complicated care of shock. It is to be used for deep as well as superficial burns. It is suitable for all parts of the body including the eyes. It is to be left in place until shock has been averted or controlled and nutrition is satisfactory. For burns of first and superficial second degree it should constitute the permanent dressing and should not be changed for two weeks or until such time that it is judged the wounds will be healed. In deep second degree and full thickness burns the primary dressing serves until the patient's condition warrants consideration of grafting procedures.

Subsequent Surface Treatment of Full Thickness Burns—All full thickness burns of more than minute extent require grafting. The sooner the wound is closed the less will be the infection, malnutrition and scarring and the shorter the hospitalization. Burns of limited extent and undoubted full thickness should be grafted within the first few hours since shock will not be present to preclude an operative procedure. Also bacterial organisms will not have had time to invade the viable tissue. A burn of limited extent of certain deep second degree but of debatable full thickness depth should also be grafted immediately in order to shorten the convalescence of the patient and intercept scarring and contractures.

The grafting of extensive burns should be delayed until shock and infection have been averted or controlled. In the first thirty-six hours during the phase of plasma loss an operative procedure is hazardous. If the blood volume has been amply maintained operation is prudent any time thereafter. On the other hand the longer the delay in grafting the greater will be the infection which in turn diminishes the blood volume, increases the operative risk and makes less likely the take of the graft. Probably only a limited area of the surface not more than 10 per cent should be grafted at any one operation. It must be realized that the wound surface is being increased temporarily each time skin is cut for a graft. Although the burn wound is closed by the graft the patient does not benefit within the first forty-eight hours.

Lack of unburned skin to be used for grafting and malnutrition of the patient as

well as shock and infection may also demand postponement of grafting.

When the primary dressing has been removed for evaluation of the wounds and it is judged that grafting cannot be undertaken a dressing similar to the primary one is applied.

Before a burn wound can be grafted it has to be free of slough for slough precludes proper nutrition of the graft and harbors bacteria. Spontaneous debridement of slough requires three weeks or longer and inevitably leaves a granulating base. Granulating fibrous tissue leads to scarring and contractures. If infection is rampant in the granulations further delay of grafting is occasioned until infection is controlled.

Debridement can be expedited by either surgical excision or dissolution by pyruvic acid dressings. For burns of limited extent which are to be grafted immediately surgical excision is the only method since the action of the acid requires a minimum of forty eight hours. An extensive burn may be debrided either by excision or dissolution.

Debridement by surgical excision has the advantage of removing completely not only the necrotic tissue but also any inflammatory barrier that may be present. The graft is laid upon freshly exposed tissue not a granulating surface and eventual scarring and contracture are diminished. The disadvantage is that in the process of excision blood is lost and the operative time prolonged.

The disadvantages of the removal by pyruvic acid are as follows. It is not effective short of forty eight hours; it is uncomfortable and progressive contamination is courted by the multiple dressings required. Its advantages are that blood is not lost during the debridement and since it is accomplished separately from the grafting procedure the operative time is not lengthened.

The area debrided by either method may be larger than can be grafted at one operation either because of lack of skin or because of the excessive operative time. The longer the interval between debriding and closure the more granulation tissue will have formed and the greater will be the scarring.

Split thickness skin grafts are to be used

in the initial grafting of full thickness burns, the thinner they are the greater the chance of survival. Excised by means of the Padgett dermatome they are best used as intact sheets and whenever possible the debrided surface is covered in its entirety. If the available skin is smaller than the site to be grafted the skin can be economically used by cutting the sheets into pieces the size of a postage stamp. These pieces are spaced as islands from edges of which the epithelium grows out to close the wound.

The grafts should be immobilized with a firm bandage and the extremities splinted.

Excessive scar formation due to infection and profuse growth of granulations before grafting may result in unsightly wounds or limiting contractures. Secondary surgical excision of the scar and grafting are indicated after all signs of active inflammation have disappeared. Thick split thickness grafts and occasionally full thickness grafts will be required.

Shock—The first complication of a burn to threaten survival of the patient is shock. The two types primary and secondary are of different etiology. Primary shock is independent of the extent of the burn and revolves around the circumstances of the accident.

Primary shock or vasomotor collapse is induced by excitement and pain. It merely endangers life and responds to the prone or head down position, reassurance and the appropriate drugs. The alarm which sometimes amounts to mania may be due to hysteria or to anoxia. Morphine is the drug of choice for the treatment of pain. Large doses are not often required since the pain is usually not excruciating or prolonged. The pain of burned hands may be relieved by elevation. If mania is present care must be taken to see whether it is due to pain, hysteria or anoxia. If it is due to hysteria barbiturates should be given; if due to anoxia oxygen alone will give relief and both the depressants morphine and barbiturates are to be avoided.

Secondary shock the result of loss of circulating plasma volume is the vicious shock and is proportionate to the extent of the burn no matter what the degree. The volume of plasma filtrate lost into a burn wound and the rapidity of its loss are so

great that measures must be taken promptly if the patient is burned over more than 10 per cent of the body surface. If 20 per cent of the body surface is burned a volume as large as the normal plasma volume may be lost into the wound in the space of eight hours.

The ideal treatment of secondary shock is its prevention for it is more effective and economical to prevent rather than to correct it once established. The principles of treatment are the same whether used in prevention or in the presence of shock and consist in the maintenance of normal nutritional environment for the unburned organs and tissues. The wound is a parasite and treatment consists of giving to the body what the wound steals from it. Since plasma loss starts immediately after the burn prevention demands instantaneous institution of therapy. For each per cent of the body surface burned 75 cc of plasma should be injected intravenously for the first twenty-four hours. Since the rate of edema formation decreases with time half of the total amount should be injected within the first eight hours. An equal volume of electrolyte solution should be given simultaneously, preferably by mouth. Isotonic sodium chloride solution may be used but an isotonic solution made up of two-thirds sodium chloride and one-third sodium bicarbonate is better since the excess of chloride is avoided. An additional 2,000 cc of fluid not containing salt is given in the first twenty-four hours in order to maintain kidney function. If the patient vomits both electrolyte solution and water as a 5 per cent glucose solution should be given intravenously. It is however more economical to give these fluids by mouth since the plasma flows more rapidly into the wound if it is diluted. If the patient is thirsty or if kidney function ceases an inadequate amount of plasma and electrolyte solution is being given. Repeated hematocrit or hemoglobin readings should be made and if hemoconcentration is present the rate of injection of the plasma is to be increased. In order to judge the adequacy of kidney function an indwelling catheter should be employed for all severely burned patients for the first thirty-six hours.

In the second twenty-four hours half of the amount of plasma and electrolyte solu-

tion required in the first twenty-four hours should be given. The peak of edema is reached usually between thirty-six and forty-eight hours. After forty-eight hours plasma and electrolyte solution are required only if inadequate amounts have been given in the previous two days. Indeed if therapy has been adequate further plasma and electrolyte are contraindicated because after forty-eight hours the resorption of edema fluid is usually under way. The flow of protein, electrolytes and water from the wound into the blood stream is greater than the loss and the body is now freed with eliminating or metabolizing the electrolytes and plasma originally given in therapy. The administration of large volumes of fluid after forty-eight hours may therefore result in overhydration and pulmonary edema. During the period of edema resorption only enough water should be given to maintain an adequate kidney function. 2,000 cc a day is usually adequate.

If an extensively burned patient is not treated within two hours shock will have occurred. This is particularly true in children. For an adult the volumes of plasma and electrolyte solution are administered according to the formula of Harkins 100 cc for each per cent that the hematocrit reading is above 45. This amount should be given as rapidly as possible and repeated until normal hemoconcentration has been achieved. Subsequent amounts of plasma to be given are calculated on the basis of the surface area formula. When the extremities are burned both the femoral and the external jugular veins may be used. The saline and water for kidney function may be given by mouth if possible as in the prevention of shock.

In patients who have been in prolonged shock acidosis may exist. In these cases it is particularly important to give one third of the electrolyte solution as sodium bicarbonate.

If plasma is not available there are the following substitutes here given in the order of preference: whole blood, albumin concentrate and gelatin. An extra amount of electrolyte should be given if the albumin concentrate is used. If none of these is available the amount of electrolyte solution is doubled, half is given intravenously with

glucose added. Such non colloid therapy results in extracellular fluid protein dilution but this dilution is preferable to the hemoconcentration of no therapy.

Patients with burns of less than 10 per cent of the body surface may not require treatment to prevent shock if adequate water is administered. There will be a slight overall plasma protein and electrolyte dilution but if the patient was healthy before the burn the body is well able to compensate.

If pulmonary damage is present it may be wise to allow a moderate degree of hemoconcentration to persist in the hope of avoiding pulmonary edema and respiratory death. Whole blood should be given in place of part of the plasma. Tracheotomy is indicated when there is obstruction of the larynx.

Use of adrenal cortical extract in burn shock therapy is not established even though there is evidence of disturbance of adrenal cortical function.

Infection.—Having survived shock the burned patient faces infection for all burn wounds except those of first degree are potentially infected. The second degree superficial wound becomes infected only when the epidermis over the blebs ruptures and the organisms on the surface can penetrate it. In the deep second and third degree burns where the epidermis is cracked infection is to be anticipated. As in the treatment of shock prophylaxis is easier than eradication. Prophylactic chemotherapy is indicated except for minor second degree burns. Infection develops rapidly and may be present within six hours.

Penicillin is the most effective drug yet available for prophylaxis and treatment. It acts against most of the gram positive organisms and when given intravenously or intramuscularly it prevents invasion of the unburned tissue. Given parenterally it is not able to control the growth of organisms in the slough of deep burns. Its instability limits its local use to wounds which can be irrigated at frequent intervals. For a 10 per cent burn 100,000 Oxford units should be given parenterally per day in divided doses. For burns of greater extent amounts up to 400,000 units per day may be given. For prophylaxis the drug should be started

immediately. In the deep burns of limited extent which are treated with immediate debridement and grafting prophylactic chemotherapy is optional.

Subsequent chemotherapy will depend upon the depth and extent of the burn. For the superficial burn nothing more than prophylactic penicillin will be needed. In the deep burns infection will remain until the wounds are debrided and grafted and chemotherapy should be continued until they are healed. The dosage of penicillin and the agents to be used in addition will depend upon the nature and virulence of the infection. Swab cultures should be taken before the primary dressing is applied and at subsequent change of dressings. The results will guide the use of chemotherapy. Heavy infection of gram positive organisms especially streptococci and staphylococci demands an increased dosage of penicillin both parenterally and locally. *Gramicidin* is useful locally; it is more stable than penicillin. The presence of gram negative organisms may indicate the use of *Dalacin* solution.

One of the *sulfonamides* may be used if penicillin is not available. The sulfonamides control only the streptococci as effectively as does penicillin. They are toxic in contrast to penicillin. Their local use must be carefully limited in order to avoid absorption to toxic levels.

Malnutrition.—The malnutrition of burns—wasting and anemia—may be abrupt in onset and extensive. To the local destruction of cells and protein by the heat and subsequent infection is added the general breakdown of reserves by the alarm reaction and infectious toxemia. Malnutrition will not be a problem in a patient with a burn of less than 10 per cent of the body surface unless the wound is severely infected. In an extensively burned patient malnutrition may be severe enough to retard the regeneration of cells and the healing.

The nutritional deficit created by the local destruction of tissue and blood is probably a minor problem. More important are the general disturbances incurred by fever, alarm reaction and infectious toxemia.

Burned patients have fever proportionate to the extent of their wounds. With a fever

there is elevation of the metabolic rate and an increased demand therefore for combustible materials including carbohydrate and fat. The main deficiency developing in a burned patient however appears to be that of protein and is engendered by the alarm reaction. As much as 40 Gm of non-protein nitrogen the equivalent of 252 Gm of protein may be excreted through the kidney daily. Muscle atrophy accompanies such loss.

The caloric and nitrogen deficits are best met by dietary measures. By the use of milk milk products eggs meat chicken and fish an enticing high protein and high caloric diet can be arranged. An intake of 200 Gm of protein and 4000 calories should be striven for and should be started immediately. If the patient is nauseated stomach tube feedings including protein digests should be resorted to. Amino acid mixtures may be given intravenously in addition to plasma and whole blood transfusions. A liberal quantity of vitamins particularly vitamin C and the B complex should be included in the diet.

Red blood cell destruction presumably the result of infectious toxemia is a prominent feature in patients with deep burns in the first three weeks. It cannot be controlled by the dietary intake of protein and iron. The reticulocyte count is not depressed but does not rise above normal until the hemolytic phase is passed. Replacement of red blood cells can therefore be achieved only by transfusion of red blood cells or of whole blood. From the fifth to the fifteenth day when the hemolytic phase is at its height patients have required on the average as much as 600 cc of whole blood per day to maintain a normal circulating volume of red blood cells.

INJURIES DUE TO COLD

The feet hands nose ears and cheeks are the parts of the body most frequently damaged by cold partly because of their exposed position and their large surface area as compared with the total volume and partly because of anoxia from vasoconstriction secondary to chilling of the skin. Injury may result directly from actual freezing of the tissues (ordinary and high altitude frostbite) or may be secondary to changes in the blood vessels brought on by long exposure to cold without actual freezing (inner ear hand or foot). Certain patients with neuroses may complain of subjective symptoms but no objective changes are demonstrable.

Actual freezing which may occur in a healthy person in a cold climate is seen in temperate climates only when a debilitated or comatose person is long exposed to a freezing temperature. However in high altitude living individuals in any climate may be transported quickly to an extreme degree of cold and may at times have to expose themselves. With any frostbite there is little pain until thawing begins then as a result of the extravasation of fluid and an inflammatory reaction the pain is excruciating. This is followed by anesthesia if the part is dead and by paresthesia or hyperesthesia if the tissues survive.

Where there is long continued local loss of heat with impairment of circulation but without actual freezing there is an initial vasoconstriction followed by vasodilatation during which the part becomes pink or red.

Following this there is progressive swelling with increasing impairment of the circulation. Even after the exposure is over thrombosis may occur and cause extension of the damage. The damage either from actual freezing or from long exposure without freezing may be superficial with only redness and swelling either with or without the formation of blisters or deep with either moist or dry gangrene of the skin and any amount of the subcutaneous tissues.

In certain persons with poor circulation and low resistance chilblains may develop

situ for exposure which within a time of seconds or minutes may freeze fingers solid. Also suitable equipment for shipwrecked persons might reduce the incidence of immersion damage to feet and hands.

After an injury due to cold has been sustained general systemic as well as local treatment should be given. The patient should be kept in a relatively cold room and hot drinks and stimulants given as indicated. The temperature of the part should be gradually raised by placing it in contact with the body of a healthy person. Some

Fig. 17.—Frostbite of the hand. Appearance six months after exposure followed by sloughing of the palmar fat pads. The fingers are smooth and glazed in appearance. The joints are stiff and painful on motion and the growth of the nails has been retarded.*

as a result of repeated exposure to cold with little muscular exercise. There is itching of the involved part and a chronic erythema develops. The skin is roughened and ulceration may result. If infection occurs the damage may be extensive.

Treatment.—Prophylaxis is most important and consists in avoiding long exposure to cold and dampness, particularly if the body is in poor condition or without adequate protection. Gloves and shoes should give proper insulation and should never be tight fitting.

In high altitude flying proper engineering may go far toward avoiding the neces-

sity of keeping the part at a temperature only slightly above freezing for several days, but this has not been accepted generally. If other methods of raising the temperature are tried every precaution must be taken to avoid overheating, since the impaired circulation cannot dissipate the heat. Care should be taken not to break the skin, hence the part must not be rubbed with snow or a wet cloth. After the temperature has been restored the part should be cleaned and wrapped in sterile cotton, then elevated in order to favor venous and lymphatic drainage.

* *Lew: Practice of Surgery*, W. F. Prior Co., Publishers.

phatic drainage and the patient moved to a warmer room.

Much consideration is being given to producing vasodilatation by various methods: (1) application of heat to the body as a whole (2) giving drugs which have a direct effect on the musculature of the blood vessels or (3) drugs which affect the autonomic nervous system and (4) blocking the sympathetic nerve trunks or peripheral nerves. According to Davis and others the drugs which could be taken early without the aid of a doctor have been a total failure. The desirability of sympathetic block is still open to debate and must be decided on its merits for each case. Passive vascular exercises have been advocated to improve the circulation.

The subsequent treatment consists in avoiding pressure or overheating and varies according to the extent of the injury. If the skin is intact active and passive motion and massage may favor the return of circulation and help maintain function. When the skin is broken infection should be guarded against by painting the area with gentian violet and covering it with dry sterile dressings. If infection occurs it should be combated by means of hot wet dressings and by removal of dead tissue incision and drainage or by amputation. If gangrene appears the part should be put at rest under aseptic conditions and separation of the dead tissues awaited. It must be remembered that the gangrene may be superficial (Fig. 17) that it is usually less extensive than it appears and that even when deep the defect can at times be repaired by skin grafting. If the entire part is gangrenous amputation is necessary.

DEMYL HAIR

INJURIES DUE TO CHEMICALS

Injuries due to drugs and chemicals are numerous, some resulting from drugs taken internally others from substances (too numerous to tabulate) applied locally which cause dermatitis of varying degrees of severity. These forms of dermatitis are treated by removal or discontinuance of the causative agent. No attempt will be made to discuss them here but for further information the student is referred to books

on dermatology or industrial medicine. The present discussion will be limited to the more severe injuries caused by acids and alkalis phosphorus magnesium and the war gases mustard and lewisite.

The diagnosis of a chemical burn in industrial or civilian practice usually presents no problem since each patient is familiar with the nature of the chemical in which he has been exposed.

Acids and Alkalis—Acids and alkalis in normal times cause the majority of chemical burns and are best treated by immediate washing and dilution of the agent with water. Large quantities of water should be applied as quickly and rapidly as possible since this not only removes the acid or alkali in the quickest possible way but also dissipates the heat generated by the mixtures of the water with the acid before it can damage the exposed tissues. This is the most important part of the treatment* but may be followed by neutralization with an appropriate chemical agent such as dilute acetic acid or dilute solution of sodium bicarbonate. If a neutralizing agent is employed care should be taken to avoid using it in such strength as to cause further injury to the already potentially damaged tissues. This is particularly true of the eye. After as much as possible of the acid or alkali has been removed with or without neutralization the wound should be treated as any other burn.

An exception to the immediate washing off of alkali with water should be made in the case of dry powders such as lime. These should be brushed off as completely as possible before washing.

Carbolic acid in concentrated form causes rapid coagulation of superficial tissues. Like other strong acids it causes a sharp pain which usually prompts its removal or neutralization. When the acid is not removed the damage is superficial since the coagulated tissues prevent deep penetration.

Carbolic acid in weaker solutions is more dangerous than the concentrated form. It is soluble to about 5 per cent in water and is seldom applied in greater strength but evaporation of water may cause its strength to increase rapidly. When first applied it may cause slight pain but soon the stage of anesthesia begins and there is no danger

signal to warn the patient of the insidious penetration. It is most dangerous when applied as an occlusive wet dressing to a small part for instance a finger. It penetrates deeply albumin is coagulated blood vessels become thrombosed nerves are made anesthetic and the part becomes cold and numb. The area is first blanched blisters may then form and finally depending on the absence or presence of infection dry or moist gangrene develops. Moist dressings of a solution of from 1 to 5 per cent applied for from five to twenty four hours have repeatedly caused gangrene. It must be kept in mind that the salves and ointments are as dangerous as the solution.

Carbolic acid should be suspected as a causative agent whenever gangrene develops in an area which is being treated with a solution or ointment of unknown nature.

Carbolic acid should be neutralized or diluted and removed by application of ethyl alcohol. The resulting wound should be treated so as to avoid or control infection and facilitate healing. Deformity should be prevented and healing may be hastened by the judicious use of skin grafts.

Phosphorus Burns—Phosphorus burn should be treated by immediate immersion of the part in water or if this is not possible the burned area should be kept covered with wet compresses since water prevents burning of the phosphorus. Particles of phosphorus should be removed preferably with the part still under water using gauze covered forceps. The area then should be washed with a dilute alkaline solution followed by 1 per cent copper sulfate solution to give a protective coating of copper phosphide to any residual particles of phosphorus. These dark particles should then be removed. After all phosphorus has been removed the resultant wound should be treated as an ordinary burn. The search for small particles of phosphorus may be made in a dark room under which condition the natural fluorescence simplifies its location.

An exception to the application of water to phosphorus should be made in the case of the pentoxide pentosulfide and pentochloride powders. These should be carefully brushed off before washing since when they are mixed with water much heat is generated and phosphoric acid is produced. If

water is already present (e.g. perspiration) the part should be flushed with large quantities of water as rapidly as possible to dissipate the heat and remove the acid.

Magnesium Burns—Magnesium burns are usually small and produce a gradually enlarging ulcer if all the metal is not removed. No neutralizing agent is available. After an aseptic preparation of the skin and injection of a local anesthetic the burned ulcer should be excised out down to healthy tissue. Following this the course and treatment are similar to those for non specific ulcer from any other cause.

War Gases—The war gases most commonly causing skin injuries are mustard gas and lewisite.

Mustard gas is a skin irritant and produces blisters with deep destruction of the skin. Contaminated clothing should be removed immediately. The liquid must be removed from the skin as soon as possible by dabbing with dry pads and never by rubbing since this spreads the liquid. Pads should be used only once to avoid spreading the liquid to uncontaminated areas.

The remaining mustard liquid or gas should then be removed or neutralized by one of the following methods: (1) dabbing with dichloramine-T in triacetin (2) removal with solvents such as gasoline kerosene carbon tetrachloride or alcohol with precautions as to spreading the irritant and the avoidance of hazards of fire (3) application of products containing active chlorine such as grade A calcium hypochlorite or sodium hypochlorite (Dakin's solution). The calcium hypochlorite may be mixed with 1 to 2 parts of water to form a paste but since this is irritating it should be washed off within three minutes. If no other neutralizing or solvent agents are available liberal use of soap and water gives very satisfactory results.

After the mustard has been neutralized the skin should be washed with soap and water and patted dry. Burns should be treated as other burns with suitable precautions to avoid or control infection and facilitate healing.

The hair must be decontaminated or clipped. The eyes should be irrigated immediately for ten minutes with 2 per cent sodium bicarbonate solution saline or plain

water, but only if within five minutes of continuation. Further treatment of the eyes should be carried out by an experienced ophthalmologist.

Lewisite,⁴ a skin irritant containing arsenic, penetrates rapidly, so that prophylactic treatment of the skin should be begun within one minute after exposure. Contaminated clothing and the lewisite should be removed with the same precautions as for mustard gas. The neutralizing agents for lewisite are different, and one of the following may be used: 1. Light per cent hydrogen peroxide is the best, but the 3 per cent solution may be used. Fresh swabs should be employed for each application, with precautions to avoid spreading the irritant. 2. Sodium hydroxide as a 10 per cent

treatment is available, the burned skin may be excised to save the patient's life by removing the arsenic. After the irritant has been eliminated the burn should be treated as for a mustard gas burn.

Dermatitis Factitia.—Dermatitis factitia (feigned eruptions, dermatitis artefacta) should be specifically mentioned here, since these lesions are frequently caused by chemicals (carbolic and other acids, alkalis, creosol, croton oil, mercuric chloride, cantharides, etc.) as well as by rubbing and other forms of trauma. The history is of course unreliable, since the patient is making every effort to deceive his family and his doctor as well. The lesions are usually few in number, they frequently appear at night and they are more commonly located on easily

Fig. 18.—Large self-inflicted eschars, probably caused by application of sodium hydroxide to which the patient had access. All lesions healed while the patient was in the hospital but others appeared two months after discharge.*

solution in 30 per cent glycerin may be used if hydrogen peroxide cannot be obtained. The skin should be swabbed with this agent, alternating with alcohol. If glycerin and alcohol are not available a 5 per cent aqueous sodium hydroxide may be used, alternating with water instead of alcohol. 3. In the absence of neutralizing reagents, the same solvents used for mustard gas (e.g., gasoline, kerosene, carbon tetrachloride or alcohol) may be used in the same manner and with the same precautions as for mustard gas. Lewisite like mustard gas can be rather effectively removed with the liberal use of soap and water.

After the agent has been neutralized or removed by a solvent, the skin should be washed with soap and water.

The blister fluid contains arsenic, and this may be evacuated to limit absorption and must not be allowed to contaminate the skin, since it is irritating. When no other

necessary parts of the body (Fig. 18). As the older lesions heal, new ones appear until the diagnosis is made or until the patient has accomplished, or failed to accomplish the purpose for which the lesions were inflicted (i.e., obtaining sympathy, avoidance of unpleasant duties, sexual gratification, etc.).

The nature of the lesion may be suspected from its artificial appearance, the absence of anything to account for its occurrence and the general reaction of the patient. Such patients stress their suffering and ill health, plead for something to be done and in general give the appearance of being overcooperative.

The diagnosis might be made by keeping the patient under secret observation. Confirmatory evidence can be easily obtained by covering the part with a fixed dressing such as a plaster cast, following which, all

* Hart. Tr. North Carolina M. Soc.

wounds heal and no new lesions develop in the protected area. The patient should not be openly accused until there is conclusive proof that he is responsible for the wounds. Even then the doctor can often let the patient know that the correct diagnosis has been made but need not actually accuse him.

Treatment may offer many difficulties and frequently causes the patient to go to another doctor. Healing can be obtained by covering the part with a protective dressing. In many cases after the patient realizes that the doctor knows the nature of the trouble he will discontinue inflicting the injuries. Certain patients however go from doctor to doctor and their treatment constitutes a major psychiatric problem.

ELECTRIC SHOCK

Etiology—The effect of electric current on an organism depends on (1) voltage (2) amperage (3) type of current (4) resistance and (5) individual susceptibility. Deaths have been reported as resulting from 46 volts. With currents alternating at from 25 to 300 cycles voltages under 250 tend to produce pure ventricular fibrillation, those over 1000 pure respiratory center paralysis and those between 220 and 1000 affect both the heart and the respiratory center. Contrary to the general impression high voltage currents are less dangerous than low voltage currents.

The amperage ($\frac{\text{voltage}}{\text{resistance}}$) is difficult to determine because of the variable resistance of the body. High amperage is usually less dangerous than low. Alternating currents of from 70 to 110 ma or a direct current of from 200 to 250 ma may be fatal if passed

through the chest. Alternating current is three to five times more dangerous than direct. Those from 39 to 150 cycles are the most fatal. As the number of cycles increases the danger diminishes. Spark discharges can be fatal by paralyzing the respiratory center. They can produce ventricular fibrillation only if the heart is struck during the vulnerable period of late systole. The resistance of the body depends to a great extent on that of the skin. Except for bone all other tissues have comparatively low resistances. The dry skin averages about 5000 ohms and when wet 1000 ohms so that a current of 100 volts (100 ma) could be fatal. With saline electrodes it may fall to 300 ohms so that a current of only 30 volts (100 ma) may cause death if passed through the chest. In a calloused palm the resistance may reach 1 000 000 ohms. Perspiration reduces resistance. Shoes shod with iron nails or moist shoes make good contact with the ground and allow a current to pass through the body. A broad surface and firm contact permit the flow of more current than smaller and lighter ones. The passage of the current through a conductor generates heat in direct proportion to the resistance producing local marks and burns.

Electric marks or contact burns are not ordinary burns. They are usually round or oval from a few millimeters to several centimeters in diameter gray to gray yellow and sharply demarcated from the normal tissue. The limbs are not affected. The lesions are odorless, painless and free from inflammatory reaction or blisters. They remain unchanged for several weeks after which occurs a slow process of aseptic necrosis and sloughing with the eventual formation of a smooth pink scar. The resultant slough is often two or three times the extent of the original lesion probably because of the disintegration of the media of arteries often far distant from the original lesion. These marks are considered the most characteristic manifestations of the passage of electricity through the body. With high or brush-discharge contacts flash or arc burns are produced. These have a temperature ranging from 2500° to 3000° C and may produce extensive lesions involving entire extremities. Metallic deposits are often found around and embedded in the burned area.

water but only if within five minutes of contamination. Further treatment of the eyes should be carried out by an experienced ophthalmologist.

Lewisite—a skin irritant containing arsenic penetrates rapidly so that prophylactic treatment of the skin should be begun within one minute after exposure. Contaminated clothing and the lewisite should be removed with the same precautions as for mustard gas. The neutralizing agents for lewisite are different and one of the following may be used: 1. Eight per cent hydrogen peroxide is the best but the 3 per cent solution may be used. Fresh swabs should be employed for each application with precautions to avoid spreading the irritant. 2. Sodium hydroxide as a 10 per cent

treatment is available the burned skin may be excised to save the patient's life by removing the arsenic. After the irritant has been eliminated the burn should be treated as for a mustard gas burn.

Dermatitis Factitia—*Dermatitis artificia* (feigned eruptions, *dermatitis artificia*) should be specifically mentioned here since these lesions are frequently caused by chemicals (carbolic acid, other acids, alkalis, cresol, croton oil, mercuric chloride, cantharides, etc.) as well as by rubbing and other forms of trauma. The history is of course remarkable since the patient is making every effort to deceive his family and his doctors as well. The lesions are usually few in number, they frequently appear at night and they are more commonly located on easily

Fig. 18—Large self-inflicted eschars probably caused by application of sodium hydroxide to which the patient had access. All lesions healed while the patient was in the hospital but others appeared two months after discharge.

solution in 90 per cent glycerin may be used if hydrogen peroxide cannot be obtained. The skin should be swabbed with this agent alternating with alcohol. If glycerin and alcohol are not available a 5 per cent aqueous sodium hydroxide may be used alternating with water instead of alcohol. 3. In the absence of neutralizing reagents the same solvents used for mustard gas (e.g., gasoline, kerosene, carbon tetrachloride or alcohol) may be used in the same manner and with the same precautions as for mustard gas. Lewisite like mustard gas can be rather effectively removed with the liberal use of soap and water.

After the agent has been neutralized or removed by a solvent the skin should be washed with soap and water.

The blister fluid contains arsenic and this may be evacuated to limit absorption and must not be allowed to contaminate the skin since it is irritating. When no other

accessible parts of the body (Fig. 18). As the older lesions heal new ones appear until the diagnosis is made or until the patient has accomplished or failed to accomplish the purpose for which the lesions were inflicted (i.e., obtaining sympathy, avoidance of unpleasant duties, sexual gratification, etc.).

The nature of the lesion may be suspected from its artificial appearance, the absence of anything to account for its occurrence and the general reaction of the patient. Such patients stress their suffering and ill health plead for something to be done and in general give the appearance of being overcooperative.

The diagnosis might be made by keeping the patient under secret observation. Confirmatory evidence can be easily obtained by covering the part with a fixed dressing, such as a plaster cast following which all

• Hart, Tr. North Carolina M. Soc.

wounds heal and no new lesions develop in the protected area. The patient should not be openly accused until there is conclusive proof that he is responsible for the wounds. Even then the doctor can often let the patient know that the correct diagnosis has been made but need not actually accuse him.

Treatment may offer many difficulties and frequently causes the patient in pain to another doctor. Healing can be obtained by covering the part with a protective dressing. In many cases after the patient realizes that the doctor knows the nature of the trouble he will discontinue inflicting the injuries. Certain patients however go from doctor to doctor and their treatment constitutes a major psychiatric problem.

ELECTRIC SHOCK

Etiology—The effect of electric current on an organism depends on (1) voltage (2) amperage (3) type of current (4) resistance and (5) individual susceptibility. Deaths have been reported as resulting from 46 volts. With currents alternating at from 50 to 300 cycles *voltages* under 200 tend to produce pure ventricular fibrillation than over 1000 pure respiratory center paralysis and those between 200 and 1000 affect both the heart and the respiratory center. Contrary to the general impression high voltage currents are less dangerous than low voltage currents.

The *amperage* ($\frac{\text{voltage}}{\text{resistance}}$) is difficult to determine because of the variable resistance of the body. High amperage is usually less dangerous than low. Alternating currents of from 70 to 110 ma. or a direct current of from 200 to 250 ma. may be fatal if passed

through the chest. Alternating current is three to five times more dangerous than direct. Those from 30 to 150 cycles are the most fatal. As the number of cycles increases the danger diminishes. Spark discharges can be fatal by paralyzing the respiratory center. They can produce ventricular fibrillation only if the heart is struck during the vulnerable period of late systole. The *resistance* of the body depends to a great extent on that of the skin. Except for bone all other tissues have comparatively low resistances. The dry skin averages about 5000 ohms and when wet 1000 ohms so that a current of 100 volts (100 ma.) could be fatal. With saline electrodes it may fall to 300 ohms so that a current of only 30 volts (100 ma.) may cause death if passed through the chest. In a calloused palm the resistance may reach 1,000,000 ohms. Perspiration reduces resistance. Shoes clad with iron nails or moist shoes make good contact with the ground and allow a current to pass through the body. A broad surface and firm contact permit the flow of more current than smaller and lighter ones. The passage of the current through a conductor generates heat in direct proportion to the resistance producing local marks and burns.

Electric marks or *contact burns* are not ordinary burns. They are usually round or oval from a few millimeters to several centimeters in diameter gray to gray yellow and sharply demarcated from the normal tissue. The hairs are not affected. The lesions are odorless painless and free from inflammatory reaction or blisters. They remain unchanged for several weeks after which occurs a slow process of aseptic necrosis and sloughing with the eventual formation of a smooth pink scar. The resultant slough is often two or three times the extent of the original lesion probably because of the disintegration of the media of arteries often far distant from the original lesion. These marks are considered the most characteristic manifestations of the passage of electricity through the body. With light or brushing contacts *flash* or *arc burns* are produced. These have a temperature ranging from 2,000° to 3000° C and may produce extensive lesions involving entire extremities. Metallic deposits are often found around and embedded in the burned area.

The final slough is usually much more extensive than the original burn. Secondary hemorrage is common. As a rule if the resistance is low the general effects are severe and burns slight; if high the burns are severe and the general effects slight.

Pathologic Physiology—Death from electricity may occur as the result of (1) primary fibrillation of the ventricles (2) failure of the respiratory center (3) ventricular fibrillation plus respiratory failure (4) prolonged tetanus of the respiratory muscles or (5) delayed death. When fibrillation occurs there are no heart sounds or pulse and the patient is unconscious; respirations continue, become exaggerated from asphyxia and fail in about two minutes, death ensuing. When the respiratory center alone is paralyzed unconsciousness occurs, respirations are absent but the heart continues to beat. There is a great fall in blood pressure and the skin is cold and cyanotic. When both the heart and the respiration are affected death occurs immediately. Some hold that in the majority of cases death from electric shock occurs as the result of uncomplicated ventricular fibrillation and that this state once established is usually permanent. Others maintain that in most cases death from electric shock is only apparent; that the victims suffer from temporary paralysis of the respiratory center and that if artificial respiration is continued until the center recovers, most of the victims will live. One case has been reported in which the patient was revived by artificial respiration after eight hours; several cases after four hours of suspended animation. In the writer's own series of fifty-eight cases 91 per cent of the victims died. Important data were available in only twenty-seven cases. Of these patients 52 per cent were unconscious, respirations were absent in 74 per cent. In all but two cases prompt pressure artificial respiration was immediately instituted and continued without interruption until recovery or until rigor mortis developed. In the fatal cases the duration of artificial respiration was four hours in one case, one and one-half hours. Eighty-two per cent of the patients died, 15 per cent as a result of falls or burns. Of the remainder 59 per cent probably died of persistent ventricular fibrillation.

Pathology—Postmortem studies regarding the nature of electric shock have been disappointing. Destruction of the media of arteries occurs frequently. When large currents are used as in legal electrocutions capillary hemorrhages are found in the cortex and in the floor of the fourth ventricle but these are not present in accidental electrocution from smaller currents. Pathologists do not agree as to whether certain minute changes occurring in the cells of the central nervous system are due to the current to postmortem alteration or to artefact. Transient albuminuria is frequent after electric shock. Cysts and hemoglobinuria may be present. Edema of the lungs has been noted post mortem in over half of thirty-seven fatal accidents from low voltage. There are no pathologic findings that are absolutely indicative of the passage of an electric current through the human body.

Treatment—When an electric accident has occurred the victim should be freed immediately of the current. If he is at a height he may fall and sustain severe or fatal injuries. At times the current may hold him fast to the conductor. In any case the flow of current must be stopped immediately by throwing the proper switch or by severing the conductor using a properly insulated instrument or an axe with a dry wooden handle or by diverting the current by allowing a metal chain to make simultaneous contact with the conductor and the ground. The charged person may be dragged from the live line by means of dry clothing or a leather belt or pushed away with a stick of dry wood. If it is necessary to touch the victim the feet should be used, never the hands. When cutting the conductor, one should turn the head from the sight of contact in order to protect the eyes from the flash. If the victim is at a height preparations should be made if possible to prevent or lighten his fall.

The treatment of shock victims is usually undertaken by untrained co-workers who are unable to judge the nature of the electrical accident. Any victim who is not breathing should immediately be given artificial respiration and the latter continued without interruption until spontaneous respirations are resumed or death is certain. Jex Blake says that only the onset of rigor mortis or the

cooling of the body should be considered as evidence of death. The prone pressure method is best. Pressure and suction devices for maintaining artificial respiration may be dangerous and their use is not recommended. Lay co workers should treat only cases of unconsciousness due to respiratory paralysis. The physician however is better qualified to determine the nature of the accident. If the victim is not breathing but there is evidence of regular cardiac action the prognosis is good and artificial respiration should be continued. If there is no evidence of cardiac function or respiration it is likely that ventricular fibrillation or cardiac arrest has occurred. If regular pulsations are noted in the neck the presence of fibrillation is more probable. A drop of ether instilled into one eye may reveal the presence of even a feeble circulation by the redness produced. The other eye serving as a control. A blunt probe introduced through the skin to lie against the ventricle may show whether the latter is normal fibrillating or quiescent. Precordial compression or the prick of a needle introduced into the heart may stimulate the arrested organ to contract normally aided if necessary by the injection of 1 cc of 1:1000 epinephrine. If this fails further attempts to institute normal rhythm whether for arrest or for fibrillation require immediate cardiac massage. A fibrillating heart is not a dead heart yet no amount of artificial respiration alone will bring back its normal beat. The cerebral circulation must be restored within fifteen minutes if the vital centers are to be viable and the cerebrum is to suffer no permanent deterioration. Thus unless the shock occurs in or near an operating room the chances for recovery from electrically induced ventricular fibrillation are practically nil. In favorable circumstances the heart is exposed quickly the condition of arrest or fibrillation determined and massage begun at once and continued until normal rhythm is resumed or death is certain. If the heart is quiescent massage alone may be successful if not success may follow the passage of a suitable electric current through the heart or the injection of epinephrine into the right heart followed by the current. If the ventricles are fibrillating the heart must first be brought to complete rest by passing the current

through it or by injecting 5 cc of 2 per cent procaine or 5 cc of 1 per cent calcium chloride into the right side followed by the current as advised by Beck. When defibrillated the heart is treated as if quiescent. Both epinephrine and calcium chloride tend to induce or maintain fibrillation. On the basis of dog experiments Wiggers although in essential agreement with the foregoing statements advises against the use of all drugs. If no facilities are at hand artificial respiration should be continued for twenty minutes in the hope that spontaneous recovery will take place. In cases of fibrillation long continued artificial respiration is oflogical in cases of respiratory paralysis in which the heart is functioning artificial respiration is indispensable. In the majority of my cases electrically induced unconsciousness was due to ventricular fibrillation and artificial respiration was of little avail. This should not deter rescuers from carrying on prolonged artificial respiration when the diagnosis is in doubt.

The use of stimulating injections is not advised. Lobeline is dangerous and may even cause the death of the patient. Oxygen inhalations may act as a respiratory depressant. Carbogen (7 per cent carbon dioxide in oxygen) combined with artificial respiration is of definite value if the patient has begun to breathe. Subjecting the victim to a physical counter shock is unjustifiable. Prompt lumbar puncture and drainage should be done if signs of cerebral irritation or of increased intracranial pressure occur. The revived patient should be hospitalized and watched for sudden cardiac dilatation or secondary hemorrhage.

All electric burns should be treated with great care. Those which appear trivial at first may later become serious or fatal because of toxic absorption, secondary hemorrhage or infection. The local treatment is in accordance with the principles set forth in the section on burns. Shock should be treated promptly to bring the blood values to normal. Surgical treatment is not advised until the separation of sloughs because of the danger of alarming hemorrhage. Skin grafting may later be necessary. Amputations should be resorted to only after all conservative measures have been tried.

Repeated roentgenograms of contact sites

should be made because of the possible occurrence even months after the shock of osteoporosis followed by spontaneous fractures and sequestrum formation. There may be optic atrophy and retinal disturbances. Flash cataract occasionally appears as late as two years. Marked disturbances of the central nervous system have been reported. Most commonly these are similar to ones which result from cerebral concussion and they may form the basis of litigation where workmen's compensation laws are in effect.

INJURIES CAUSED BY IRRADIATION

Definition—The term radiodermatitis signifies an inflammation of the skin or orificial mucous membranes caused by exposure to x rays or to radiation from the radioactive elements.

Etiology—Radiodermatitis results from the irradiation of tissue beyond the tolerance point.

Pathology—The first histologic evidence of acute radiodermatitis does not differ essentially from that of an ordinary inflammation. Thereafter the picture depends on the size of the dose administered and the radiosensitivity of the tissue. If the injury is beyond the possibility of immediate repair there is degeneration of the epithelium of the skin and the cutaneous appendages of endothelial cells, collagen and elastic tissue. When the injury is very severe necrosis and ulceration result. With the exception of mild injuries, repair is seldom complete. Degeneration leads to atrophy of the epidermis, sclerosis of collagen, marked changes in the elastica and a modification of function of or complete loss of the cutaneous appendages. In so-called x ray or radium skin (chronic

radiodermatitis) almost every deviation from the histologic normal may be seen. The principal characteristics are atrophy of the epidermis with loss of papillae, badly degenerated atrophic or sclerotic dermis, clumping of degenerated elastic tissue, thin walled markedly dilated vessels, loss of appendages and necrosis. The epidermis may undergo hypertrophy at the edge of the ulcers and in other areas leading to keratoses and cancer.

Symptomatology—Radiodermatitis may be either acute (first, second or third degree) or chronic.

First degree radiodermatitis consists of erythema (redness) which usually appears about the fifth day although it may be delayed several days or even a week or two. When the dose is sufficiently large it may appear within a day or two. When a second degree injury does not develop the erythema endures for from one to three weeks and then slowly disappears either with or without temporary pigmentation. The hair is likely to fall out about the third week, the alopecia being either temporary or permanent. Subjective symptoms consist of a sensation of heat and perhaps some pruritus. A first degree radiodermatitis may be followed by such sequelae as atrophy and telangiectasia, keratoses and even cancer.

Second degree radiodermatitis in addition to more intense erythema is characterized by edema and exfoliation and perhaps superficial ulceration with or without crusting. During the acute stage there is a burning pain. Desquamation occurs during the third week and permanent alopecia results. Spontaneous healing occurs in from one to several months. Sequelae such as cicatrix wrinkling, pigmentation, depigmentation and keratoses usually occur. Eventually cancer is likely to develop.

Third Degree—When the dose is sufficiently large the first and second degree radiodermatitis is followed by a third degree injury. This is characterized by severe inflammation, excreting or unbearable burning pain and necrosis involving the true skin, perhaps the subcutaneous tissue and even the underlying muscles. The necrosis is usually of the dry type and lasts for many weeks or months. Eventually there is a slough which is generally thrown off leaving

a deep indolent ulcer with abrupt margins and a glistening base. Depending on the size and depth of the injury, there may or may not be spontaneous recovery in the course of months or years. If not, the pain eventually disappears, and the indolent ulcer remains as a cancer menace. Even in the case of more or less complete spontaneous repair, the result is "x-ray or radium skin," which likewise is always a source of danger.

Chronic Radiodermatitis.—By this term is meant either the sequelae which result from acute injuries or those which result without an antecedent acute inflammation as a result of the administration of small doses over too long a period of time. The condition is commonly called "x-ray or radium skin." It may have one or all of the following objective signs and symptoms: telangiectasia, irregular pigmentation and depigmentation, atrophy, recurrent ulcerations, keratoses, indolent ulcer and cancer. Telangiectasia and atrophy develop, as a rule, within a year or two. Keratoses are more likely to appear several years later. Cancer may appear anywhere from a few to many years later. Subjective symptoms are either mild or absent.

Diagnosis.—As a rule, the diagnosis is easily made. In the case of acute radiodermatitis, there is the history of irradiation of the affected area followed by the sequence of events as outlined under symptomatology. Other inflammation, such as eczema, psoriasis, etc., may mask a mild radiodermatitis, but there is no entity that provides the same symptom complex or that will for long camouflage acute radiodermatitis. The same statements can be applied to chronic radiodermatitis, except that the latter may be confused, by the inexperienced, with conditions such as atrophic and keratotic eruptions caused by arsenic, xeroderma pigmentosum, and sailors' or farmers' skin. A first degree radiodermatitis must be differentiated from the "electric" erythema that sometimes occurs within a few hours after an x-ray exposure and endures for only a day or two.

Prognosis.—Because of the degenerative changes and sequelae that follow excessive irradiation, the tissues should never be exposed to amounts that exceed toleration, except when such treatment is specifically indicated and when the physician is justified

in administering very large doses as, for instance, in the case of serious or malignant conditions (cancer, certain of the lymphoblastomas, etc.). In about 25 per cent of the

Fig 19.—Third degree radiodermatitis of the back, eight months' duration. Slough has been thrown off leaving an indolent ulcer. Pain, which was unbearable for months, has lessened. Eventually a plastic operation was necessary.

Fig 20.—Chronic radiodermatitis duration of many years. The area shows many sequelae—eczema, atrophy, hyperplasia, pigmentation, depigmentation, telangiectasia, keratoses and, at the lower pole, ulceration and early carcinoma.

patients with cutaneous sequelae, cancer sooner or later develops.

Treatment.—Radiodermatitis of the first and second degrees requires no more than

soothing topical applications. Severe third degree radiodermatitis often necessitates surgical treatment. As soon as the necrosed area is well defined it should be excised. When all the badly injured tissue is removed pain ceases at once granulations appear and the wound if small cicatrizes. When the area is extensive skin grafts a sliding flap or a tubular graft may be necessary. The essential requirement is the removal of all badly injured tissue regardless of dimension depth or parts involved. Proper surgical treatment insures immediate cessation of severe pain and prompt recovery and there is no 'x-ray skin' to be a menace throughout life. Excellent results are often obtained with the fresh jelly like substance from the leaf of the *Aloe vera* plant. The ulcer is dressed twice daily with this substance. Proprietary preparations containing *Aloe vera* have not proved satisfactory.

Areas of chronic radiodermatitis require no special treatment unless there is immediate danger of cancer in which case excision or a plastic operation is indicated. Also such treatment may be indicated for cosmetic or esthetic reasons or for relief of impaired function as for instance ectropion, sclerosis of buccal commissures, etc. Titan glectasia can be made less conspicuous by means of blistring doses of water cooled ultraviolet rays administered under pressure or by means of electrolysis or the high frequency current. Nothing can be done for atrophy except excise the area. Individual keratosis when small can be destroyed with electrodesiccation. They can be temporarily eradicated with x-rays or radium but most authorities believe that such treatment is contraindicated.

Radium Injuries—These are essentially the same as those caused by the roentgen rays but there are detailed differences. Beta rays from radium element or radon (radium emanation) are comparatively superficial in effect therefore the injury is more superficial repair is more rapid and more complete and there is less likelihood of disfiguring and dangerous sequelae. Nevertheless the more penetrating beta particles can cause a serious injury to the true skin. Implantation of radon may lead to serious injury to the subcutaneous tissue bones vis-

cera etc. Heavily filtered gamma radiation administered from a distance may cause very serious injury to deep structures and viscera.

Deep Injuries Caused by X-Rays and Radium—Large quantities of heavily filtered x-rays or gamma rays and the ingestion of excessive amounts of radioactive water may cause serious injury to subcutaneous tissues muscles bones and viscera. The pathology is essentially the same as that of radiodermatitis. The symptomatology depends naturally upon the particular part or organs affected.

Certain tissues are radiosensitive while others are radioresistant. Embryonic tissue young cells cells at or near the phase of division physiologically active cells and lymphoid tissue are radiosensitive but all other normal tissue is relatively radioresistant. The degree of damage depends on radiosensitivity, the quantity and quality of radiation and the amount of absorption by overlying layers of tissue. Partial complete temporary or permanent azoospermia is easily effected. Irradiation of the ovarian regions may cause sterility. Abortion can be produced. The effect on the hematopoietic system may result in aplastic anemia lymphopenia etc. The gastrointestinal tract and other viscera may be functionally injured. Catarrh can be produced. Severe injuries to important tissues may result in invalidism and death.

Injuries Produced by Ultraviolet and Infra Red Radiation—By infra red radiation is meant heat. Carelessly or excessively employed heat may produce severe and serious burns. Heat in susceptible persons causes the condition known as erythema ab igne.

Excessive exposure of large areas of the body to solar radiation or to similar radiation from artificial sources may cause serious illness and even death. Local burns caused by ultraviolet rays are uncomfortable but they heal rather promptly usually without leaving permanent sequelae. Frequent exposure to such radiation over a period of many years in the presence of idiosyncrasy or sensitivity may give rise to sailors or farmers skin a condition simulating chronic radiodermatitis and xeroderma pigmentosum. Ultraviolet radiation may pre-

precipitate an attack of lupus erythematosus and herpes simplex. It is a factor in the production of the symptom complex of pellagra and xeroderma pigmentosum.

V. THE SKIN AND SUBJACENT TISSUES

WOUNDS

A wound is a solution of unity in any part of the body by an external instrument. They receive their differences from their magnitude, part wounded and their cause' (James Conk of Warwick). The repair of a wound is effected by the activity and growth of living cells save for what may be accomplished by contraction. The role of the different cells varies only to meet the demands of the wound. And when healing is complete the growth of new tissue from living cells ceases.

Viewed in this light it is perhaps helpful to regard every wound as a new growth in which paradoxically every effort should be made to promote its growth knowing that some biologic principle will terminate the process when healing is complete. With this idea in mind one is more likely to evaluate properly one's efforts to assist and what is probably more important to develop an alertness to meet the ever changing demands of different kinds of wounds or even of a given wound during the course of healing.

It is well nigh a law of nature that the growth of living things is best when food is plentiful and when there are no handicaps to divert the energies of the cells from the process of growth. In a broad sense the physician's responsibility in connection with a wound is to endeavor to provide the cells which must grow and heal the wound with the best possible food and to rid them of the handicaps which may stunt their activities or even destroy them. It is perhaps not generally realized that all the established principles of wound healing have a rationale in one of the two aims. Let us now briefly review them.

Necrosis, Delirium, Foreign Bodies.—These terms are self explanatory and have reference to the presence in wounds of substances other than the living cells of tissues. Discussed by Paracelsus (1493-1541) and dramatized into a legend at the battle of Danvillers in 1552 by Paré who ran out of boiling oil it has since become firmly

established that any of these substances in a wound is a definite handicap to the processes of healing. Dead or devitalized tissues not only serve as excellent food for the growth of bacteria but also divert the energies of living cells from the problem of repair to the problem of elimination of foreign materials.

Foreign bodies or tissues long dead in a wound are easily recognizable by their appearance. But this is not enough. It is absolutely essential for the physician to realize that tissues deprived of their blood supply by trauma, tight ligatures and sutures must die even though at the completion of the repair of a wound no apparent changes can be detected in their appearance (Fig. 21).

Rest.—The value of rest to the processes of a healing wound was fostered by Baron Larrey and amply confirmed by Billroth and others. Motion in a fresh wound brought about by joint or muscular action disturbs the medium in which the cells are growing and invites infection by causing minute hemorrhages and the death of countless delicate growing cells. Besides avenues for the spread of infection may be opened up in the granulation tissue. This principle is applicable in all wounds, not just those involving bones.

Blood Supply.—The living cells which heal a wound must in the final analysis receive their energy from the circulating blood. This is readily observed in the vast differences in the healing of wounds in sick and in well aged and young debilitated and robust persons. In the treatment of a wound it therefore becomes the physician's obvious duty not to neglect any measures that will enhance the blood supply to the area involved. A consideration of this factor will indicate to the thoughtful surgeon the position in which the wound should be kept in order to secure for it the maximum blood supply. The crippling effect of excessive edema on blood supply will indicate the necessity for elevation of an injured extremity and the avoidance of tight circular dressings.

with a tourniquet like effect. If the arterial supply of the part is greatly reduced as compared with the venous return it may be

be used only to approximate living tissues not to strangle them and therefore should be tied no tighter than to accomplish

wise to use a dependent position. With due consideration of this principle of blood supply one can imagine a wound literally crying out to the physician that sutures are to

gentle approximation that ligatures are for the purpose of controlling hemorrhage and not strangulating to death the living cells and should therefore be tied no tighter than

is required by the simple need of controlling hemorrhage.

Not only is the quantity of the blood supplied to a wound important, but also its quality. It has been shown by Thompson, Raydin and Frank that hypoproteinemia seriously retards wound healing in the experimental animal by interfering with fibropla-

When available, laboratory determinations of the hematocrit, plasma proteins, blood chlorides and vitamins give useful information as to the condition of the blood.

Hemostasis.—Hemorrhage in a wound separates living tissues and increases the amount of work the living cells must do to bridge the defect. It is a good medium for

Fig. 22.—Schematic illustration of (A) a closed fresh wound, (B) a fresh open wound and (C) the secondary closure of a granulating wound. In all three instances the healing processes are essentially the same. The fibrin (represented in solid black) serves as a medium for the growth of granulation tissue and epithelium.

sia. Severe degrees of vitamin C deficiency likewise prevent strong wound healing, though by a different mechanism—interference with the formation of the intercellular cement substance. Lanman and Ingalls have reported excellent laboratory experiments on this point, and Lund and Crandon have performed human experiments that indicate that minor degrees of C avitaminosis probably are not very important from the standpoint of wound healing.

the growth of bacteria and thus encourages the development of infection. By tension it interferes with the blood supply of living cells and retards their growth. In effect it is a foreign body that must be removed. Yet the securing of ideal hemostasis does not justify the use of unnecessary ligatures and sutures, for they, too, are foreign bodies and interfere with blood supply.

Granulation Tissue.—Granulation tissue is essential to the healing of every wound

In this sense there is no difference except in degree when a wound heals by first second or third intention whether it is clean or infected. In a clean wound accurately approximated the granulation tissue grows in the medium in the small crevice between the cut edges and the epithelial cells grow over the narrow surface (healing by first intention). If the epithelial edges are widely separated the granulation tissue grows in the medium on the surface of the wound and epithelium grows over the wide gap

a poor blood supply the growth of cells to heal the wound cannot proceed.

Besides the essential part granulation tissue plays in healing of a wound it is in the absence of epithelial and endothelial protection the body's best defense against the invasion of bacteria. Years ago Billroth reported the following experiments to his students. If you inject a drachm of putrid fluid into the subcutaneous cellular tissues of a dog the result will be inflammation, fever and septicemia. If you make a large

Fig. 23—A granulating wound showing new growth of epithelium from the wound edges into the flaps. The vessels and the lymphatics are closed. When there is no traumatization there is no absorption and the underlying tissues are best protected. B An open fresh wound without fibrin showing the open vessel and plates. Absorption takes place rapidly from such a surface.

(healing by second intention). When the edges of a gaping granulating wound are approximated the granulation tissue grows in the medium between the approximated surfaces and the epithelium over a narrower area (healing by third intention). There is no essential difference even though as shown in Fig. 23 B and C there is usually infection and in C there are always bacteria which may or may not give the clinical evidences of infection. Essential to the healing of any wound is this medium (coagulum) in which grow the cells which form granulation tissue and epithelium. When it is destroyed by bacteria, chemicals or dressings or when its formation is prevented by

granulating surface on a dog and dress it daily with charpie soaked in putrid fluid it will have no decided effect. On the borders of the inflammatory new formation the lymphatic vessels are closed on the granulating surface there are no open lymphatic vessels hence no resorption takes place. Therefore protection of the granulation tissue and its surface cell medium from traumatization and insults of any nature becomes of paramount importance in the consideration of wound healing (Fig. 23).

Temperature.—The effect of temperature on the growth of cells in vitro or of bacteria on a culture medium is well known. It is probable that the ideal temperature for the

healing of a wound is normal body temperature and that an effort should be made to approximate it with regard to the dressings and atmospheric conditions for a wound.

Bacteria—Infection is the greatest handicap to the healing of wounds but it is certain that bacteria often receive the blame when in reality the infection is due to failure of the surgeon to observe some of the fundamental principles of wound healing. All wounds even though made by the surgeon with the most meticulous asepsis receive some bacteria on their surfaces. The sterility of a wound is relative and cannot be made and kept absolute by any known means. In this sense practically every open wound possesses the potentialities in varying degrees of becoming clinically infected. Many times the development of clinical infection is not due so much to the bacteria which healthy living cells could have handled but rather to the debris and necrosis left in the wound or produced by the surgeon's roughness, the necrotizing effect of too many tight sutures and ligatures or the use of germicides which destroyed countless delicate invisible living cells. This delicate bacterial food of debris and dead or devitalized tissue is frequently the kindling of a conflagration that need never have occurred. Yet bacteria receive the blame and the conscience of the surgeon goes free.

When considering the use of a bactericidal agent in an open fresh wound one is confronted with the fact that if the agent is capable of killing micro-organisms it is capable also of killing or damaging the delicate living cells. Surely the use of every bactericidal agent involves some sacrifice of the other fundamental principles of wound healing. The harm which has resulted from pouring antiseptics into fresh wounds cannot be estimated.

The sulfonamides and penicillin are not generally classed with the other antiseptics and there is evidence that small amounts of these substances may be used without injury to tissues. The extent to which these agents should be used locally is still unsettled because of their great effectiveness when administered systemically. However many careful surgeons feel that it is advantageous to use them locally as well. Sulfanilamide is perhaps the safest of the sulfon-

amides for this purpose because its high solubility reduces its chances of caking.

From this brief consideration of bacteria in wound a few general rules may be deduced:

1 With regard to a deliberately planned or operative wound it is the duty of the surgeon (a) to reduce to a minimum by aseptic precautions the bacterial contamination of the wound and (b) to leave the wound in the best possible state to deal with the inevitable bacterial contamination.

2 With regard to a fresh traumatic wound it is the duty of the surgeon (a) to remove all foreign bodies or dead or devitalized tissues which are excellent encouragement to the growth of bacteria, (b) to remove in a way least harmful to the living cells the bacteria on the surface of the wound and (c) to leave the tissues of the wound in the best possible state to cope with the bacteria not removed.

3 With regard to an infected wound it is essential to realize (a) that organisms are growing, (b) that they have penetrated living tissues and may be destroying them, (c) that unnecessary cutting procedures may open up channels for widespread infection, (d) that drainage to the point of complete release of all tension is desirable, (e) that absolute rest of the part is vital and (f) that the harm to living cells from certain antiseptic solutions (especially Dakin's solution) may be outweighed by their value in the control of the infection. Within six hours from the time the wound is received it is usually safe to assume that the bacteria are on the surface and the wound may be treated as any fresh soiled wound. After six hours judgment comes into play as to whether the wound should be regarded as soiled or infected. This depends largely on the character and location of the wound, the severity of the soiling and the nature of the bacteria which may have entered the wound. If a wound is not treated until twelve or more hours after its occurrence it should be regarded as infected.

4 Open granulation tissue should be regarded as infected. There are always bacteria on its exposed surface, hence surgical trauma to such an area may lead to local exacerbation or even spread of this infection. Such areas should be encouraged to

close as promptly as possible. In the case of large areas this will usually require skin grafting after the bacterial flora has been rendered as favorable as possible by chemotherapeutic agents. With smaller areas it is sometimes justifiable to close the wound by secondary suture (healing by third intention).

TREATMENT OF WOUNDS

'The proper treatment of wounds is to be regarded as the most important requirement for the surgeon' (Bilroth).

In the treatment of a wound it is essential to remember that the life of the patient is important. Under conditions of extreme emergency, such as terrific hemorrhage, severe shock or other concomitant injuries, the use of many or even all the fundamental principles of treating wounds often must be modified or even completely ignored. A patient who needs blood or some other fluid intravenously for shock should not first have his wound treated. A patient with a fractured skull or a crushing injury of the chest may require nothing for a distant wound save a bandage and rest. I have thrust an unsterile finger unhesitatingly into a punctured wound of the subclavian artery in order to prevent the patient from bleeding to death.

In other parts of this book are discussed such conditions as shock, hemorrhage, fractures, injuries of joints, blood vessels, nerves, and viscera, and sucking wounds of the chest. In the remainder of the present discussion it is assumed that it is possible to treat the wound ideally; it must be realized, however, that the above named conditions, and perhaps others, may have to take precedence over the consideration of a wound. This point cannot be stressed too strongly for a wound is often treated at the expense of a life which may be hanging in the balance from some other cause.

It may be assumed that with the modern methods of technique there is not a wide variation in the actual bacterial contamination of surgical wounds. However, it is generally agreed that some bacterial soiling occurs in all so-called clean wounds. In many instances failure of the wound to heal properly is directly traceable to the burden of insults unnecessarily heaped on the tis-

sues by the operator and his assistants. Viewed in this light there was never a truer statement than that of Romans in which he says: 'The patient's best defense against infection lies in the perfection of the operator's technique.' In the performance of delicate operations and with presumably the same bacterial contamination one surgeon may obtain an infected wound while another may obtain primary healing.

The obvious conclusion from these facts is (1) to leave the cells of the tissues of the wound in the best possible state of health to combat the bacterial contamination and (2) to remove from the surface of the wound without damage to the living cells as many as possible of the bacteria.

There are many ways in which a surgeon can make an effort to leave the tissues in the healthiest condition. It is important to plan the incision so that the operation will interfere least with the blood supply and so that all skin flaps and surfaces of the wound will receive an adequate supply of blood for the growth of living tissues. Sharp dissection with a knife is least damaging to living tissues. The long ends of blood vessels that project beyond a ligature should be removed. As few clamps as possible should be used when ever clamps are necessary. A definite effort should be made to grasp only the bleeding vessels. Pressure with gauze for a few moments on the freshly cut surface of a wound may reduce by 75 per cent or more the number of clamps which might otherwise have been used. The longer a clamp is left hanging in a wound the more thoroughly is the bite of living tissue devitalized. Tissues which in the judgment of the operator will not bleed on removal of the clamps should not be tied. All non-viable tissue, whether caused by ligatures, sutures or trauma, should be excised if possible. The use of clamps on the peritoneum and other tissues solely for the purposes of traction should be eliminated or reduced to a minimum. The long-continued use of self-retaining retractors may produce venous necrosis. The 'wiping' of fresh wounds is inexcusable and worse than throwing pepper into the eyes of an infant. The blood can be just as effectively removed by suction, flushing with normal salt solution or the gentlest sponging and with infinitely less damage to the living cells. Sutures

should rarely, if ever, be employed in fat or muscle; they inevitably lead to early necrosis and are of little value as far as approximation is concerned. The fact that tight sutures in the skin may lead to a cutting necrosis is a strong hint as to their effect on the more delicate underlying tissues.

Fig. 24—Illustrating the through and through silver wire closure of a contaminated abdominal wound. This method avoids the foreign bodies of the sutures in the wound and also disturbs the blood supply much less than the usual layer closure.

Foreign body drainage of a "clean" planned wound by means of drains or tubes is almost never employed. When there is known to have been serious bacterial contamination or when there is likelihood of considerable oozing of blood, deliberate provision is made for gaps between the skin sutures. In the case of such a wound in the abdomen, no sutures are placed in the line

(Fig. 25). The wound is placed in the position of optimum circulation and kept immobilized when necessary, especially during the period of recovery from anesthesia. Unless indicated by pain or evidences of infection or hemorrhage, the wound is left undisturbed until it is thought desirable to remove some of the stitches.

Traumatic Wounds.—In the case of all traumatic wounds, bleeding of any consequence is first controlled, preferably by elevation of the part and direct pressure on the wound or, when absolutely necessary, by clamping individual vessels. In the hands of a competent surgeon the use of a tourniquet to control hemorrhage from a wound is rarely necessary.

Fig. 25—A diagram showing the method of dressing a fresh traumatic wound which has been properly cleaned and closed.

of incision, in order to avoid their necrotic effects; instead, the wound is closed with through and through silver-wire sutures, far removed from the edges of the wound (Fig. 24). Moist dressings are applied and kept moist for a considerable time by means of a rubber protective so that tension of the wound may be relieved by seepage during the period of edema or slight hemorrhage

Traumatic wounds may usually be classified as incised, contused, lacerated, penetrating or complicated or as due to animal or insect bites. These designations are self-explanatory, being used to indicate the main attribute of the wound or its etiology.

Incised Wounds.—In the case of a simple incised wound, when inspection reveals no damaged tissue, the problem is largely

one of controlling hemorrhage and washing the wound and surrounding skin in a manner that will do the least harm to living cells and yet will remove the blood clots and the vast majority of surface bacteria. Harmless bleeding during the process of washing may help to remove the bacterial contamination of the surface.

In the case of the cleaner wounds produced by relatively sterile objects cleansing of the surrounding skin with soap and water, alcohol and ether and careful irrigation of the wound with sterile salt solution or water will usually suffice. When fine particles of dirt have been ground in or the tissues have been stained with grease (or any other substance) gentle but thorough cleansing of the wound with a soft sponge and white soap should precede the irrigation with salt solution or water. Good tap water may be used without hesitation when sterile water or salt solution is not available. For this a general or local anesthetic may be required. Each has its disadvantages but it is well to remember that procaine and most of the other local anesthetic agents are derivatives of para-aminobenzoic acid and that they antagonize the bacteriostatic action of the sulfonamides.

After thorough but gentle cleansing the wound may be lightly dusted with sulfonamide powder; the harsher antiseptics which are used for skin preparation should not be used.

After the surrounding skin and wound surfaces have been carefully cleansed the field of operation has been re-draped and the operator's glove has been changed the wound is repaired as indicated with and without drainage. Only the very essential sutures for the repair of nerves, tendons and fascia are buried in the wound. The skin edges are approximated loosely and a moist dressing as previously described is applied. For a small incision approximation of the skin edges with strips of sterilized adhesive tape often suffices.

Contused Wounds.—When the skin is visible and the associated deeper injuries such as to blood vessels or a viscus do not demand treatment it is always better not to convert a contused wound into an open wound. The skin even though severely excoriated may yet serve as an excellent protection

against bacterial invasion. It should of course be carefully cleansed with soap and water and irrigated with salt solution or water. Single or repeated aspiration of old blood may keep an excoriated skin from sloughing. Moist warm fomentations of boric acid or salt solution may enhance the circulation to the point of survival of the skin.

When the skin is completely broken or damaged to the point of inevitable sloughing it is better to open the contused wound and treat it as though it were a lacerated wound.

Absolute rest may be vital to the healing of a contused wound; it prevents further trauma from muscular motion and decreases tension by lessening hemorrhage and edema.

Lacerated Wounds.—All bleeding of any consequence is first controlled preferably by elevation of the part and pressure or when absolutely necessary, by clamping individual vessels or using a tourniquet. The skin about the wound is shaved, washed with white soap and water, alcohol and ether and possibly painted with some non-irritating skin antiseptic. None of the alcohol, ether or antiseptic should enter the fresh wound. Next sterile draping is done as though for a clean operation. If any clamps were placed to control hemorrhage they are held up by an assistant during the preparation of the skin. If the operation is to be done under local anesthesia the infiltration of the skin is made well away from the edges of the wound. With this preparation the clamps are removed (now under a tourniquet if necessary) and the wound is packed with a piece of dry gauze. The wound as well as the skin edges is now carefully excised by sharp dissection. During this process it is desirable to protect the new raw surface with moist flat gauze sponges and not to contaminate the wound further by exposing the dry pack. Often the wound with the gauze pack inside can be removed in toto without any serious break in technique. At the completion of the debridement the tissues should appear healthy. For fat and subcutaneous tissues the appearance is the best guide; for muscles their ability to contract is a useful guide.

The wound is now ready for careful wash-

ing with sterile water or salt solution. During this process, the wound is usually rubbed gently with the gloved finger. If, for any reason, complete excision cannot be performed, such as the presence of exposed nerves, blood vessels and grease-stained or dirt-stained living tissues which should not be excised, it is often essential to scrub the wound with white soap and water before using the salt solution. In certain locations, particularly on the face and scalp where it is usually desirable to save every bit of viable tissue, it is often best to begin with soap and water in order to remove all dirt

there will be free seepage from the wound into the moist dressing. Usually it is far better to use no skin sutures which may in any way imperil the blood supply to either side of the skin edges. To tack a flap of skin loosely back one-half inch or more from the opposing edge is one of the hardest things in the world for a young surgeon to do. An avulsed flap of skin is far more useful alive and unsutured than dead from the anemia of the tension of the sutures which place it "beautifully" back into position. Besides, wound healing is less complicated if there is no sloughing after the debridement. It is

FIG. 26.—A. An avulsed flap of skin held back in place, unsutured but viable. B. An avulsed flap of skin sutured and doomed to necrosis as a result of anemia due to tension. In A a very slight scar results. In B skin grafting is often necessary.

and grease and then to follow this by trimming away the obviously devitalized tissues and the ragged skin edges in preparation for proper closure of the wound. After this, the wound is washed with salt solution although a complete excision had been done.

After the operative and cleansing procedures, the skin around the wound is again cleansed, dried and repainted with an antiseptic, gloves and gowns are changed, new dressings are applied and a fresh set of sterile instruments and supplies is employed for the closure.

The fewest possible ligatures and sutures are placed in the wound. Skin sutures are tied loosely and are widely spaced, so that

amazing with how little scarring even a large open wound will heal if there has been little or no loss of skin (Fig. 26).

Many factors may make it inadvisable to close a lacerated wound even after debridement; among these are the generally poor condition of the patient, the poor blood supply, the great loss of skin and subcutaneous tissues, the incomplete debridement, unusually virulent soiling and the attempt to save vital structures that cannot be satisfactorily cleansed. In such instances the wound may be dusted with sulfanilamide crystals filled with petrolatum grudge, dressed and immobilized for many days, unless pain or fever indicates the presence of infection.

After the protection of granulation tissue has formed the wound may be closed by the grafting of skin or secondary suture. Experience in the management of war wounds has led many military surgeons to use this method routinely, at least for all major injuries.

In some instances where there is doubt about the completeness of the toilet of the wound or where the patient's condition does not justify primary closure the wound may be prepared for delayed primary closure. It is simply packed loosely with gauze moistened in salt solution or a solution of sulfathiazole and immobilized for from one to three days. If the wound looks clean and uninfected when the gauze is removed it may then be closed.

It must be realized that there are many conditions and circumstances under which the ideal therapy of a traumatic wound is unpracticable. Under such circumstances the only course of procedure is to make a logical compromise. Perhaps this can best be illustrated by relating the following personal experience.

Not long ago a friend brought his boy hurriedly to my home because of a laceration of the end of the thumb. If the boy had not held his wound under running water the father would not have been so worried; he would have put some lime on it and wrapped it up. As it was he was afraid of an infection from the water. He was therefore surprised when after cleansing the skin about the wound with benzoin and then cutting away some dead fragments of skin, I had the boy sit on a stool by a sink and run warm water over the wound. After the lapse of ten or fifteen minutes while the father and I discussed fishing a large amount of petroleum jelly was placed on the wound and secured in place by a soft dressing incorporating a splint to immobilize the thumb. The hand was then placed in a sling. The father was instructed not to bring the boy for an inspection of the wound for a week unless he showed an elevation of temperature or complained of pain. No antiseptics were used in the open wound. There was practically no pain or fever. At the end of a week the wound was healed.

The father, like thousands of other persons of his generation, had been imbued since birth with the necessity of using iodine or some antiseptic to kill the germs in a wound. He had never seen a wound that healed without becoming red and painful. He could not understand why I had used a splint or cut away the fragments of dead tissue. To him the one essential on such an occasion had always been to kill the germs at whatever cost in pain, suffering and infection.

This father's attitude reflects I believe the viewpoint of the average layman today with regard to the

handling of trivial wounds and probably that of the vast majority of physicians with respect to all wounds.

Penetrating Wounds.—These wounds may be particularly serious because of the implantation in them of foreign substances such as boot leather clothing or stable dirt. Besides, the anaerobic conditions of such wounds especially encourage the growth of the tetanus organism. The treatment naturally varies with the appearance of the wound, its location and the circumstances under which it occurred. Penetrating wounds from high velocity bullets, clean instruments or objects long exposed to sunlight and drying are often best treated by careful cleansing of the points of entrance and exit, immobilization and a position of optimum circulation while those from shrapnel, slugs or nails about a barn or in moist earth will demand the complete excision and therapy described foracerated wounds. When there is fear of tetanus or dissatisfaction with the debridement it is far better to leave a wound wide open to heal by secondary intention. (See the section on Tetanus.) The clothing may be a determining factor. In a war in China one winter most of the missiles carried sheep's wool into the tissues and consequently had to be excised.

Bites and Stings.—The bites of animals, especially those of human beings, are unusually dangerous. The wounds are deeply inoculated with a great variety of microorganisms which often appear to work synergistically to produce extensive necrosis and cellulitis. When such a wound is seen in the first six hours it should be completely excised if this is possible. Unfortunately many of these wounds occur on the hands where little tissue can be sacrificed. Here the wound should be laid wide open, thoroughly cleansed and packed open. The part is splinted and chemotherapeutic instituted.

When the animal is known to have had rabies, the Pasteur treatment or one of its modifications should be instituted promptly. This is usually necessary also when the animal cannot be traced. If the animal appears normal the proper course is to keep it under observation and start antirabies treatment of the patient only in the event that the disease develops in the animal.

Insect bites except those bearing a strong poison such as that of certain spiders, had

best be treated by surface cleansing and moist dressings and afterward if necessary as infected wounds. The wounds inflicted by certain snakes, spiders and other poisonous insects should be completely excised, cleansed and not closed. Antivenoms have been developed for many of these poisons and should be used promptly. Even when the species of snake is not known it is often practical to use a polyvalent antivenom made up for all of the poisonous snakes prevalent in the region of the accident.

Complicated Wounds—Most of these conditions are considered elsewhere in this volume under such subjects as injuries to the thoracic and abdominal viscera, compound fractures, open joint injuries and lacerations of nerves, tendons and blood vessels. Even in such wounds the fundamental principles of wound healing discussed in the first part of this section obtain; they are modified only to suit the peculiar conditions.

Infected Wounds—Infection of a wound differs from soiling in that organisms have started to grow and may have invaded the living tissues. Under six hours it is reasonable to assume that this growth has not progressed very far and the wound may be treated as one with surface bacterial contamination. (This section is not concerned with the treatment of spontaneous infections: boils, carbuncles, erysipelas, lymphangitis, tenosynovitis, fascial space infections and other conditions which are discussed elsewhere in this book.)

Prevention of infection in a deliberate or planned wound is the real cornerstone of modern surgery. By and large it is being done fairly satisfactorily, although a more conscientious application of all the principles of wound healing would improve the results. The real problem of today is prevention of infection in accidental or traumatic wounds, since the use of iodine and other powerful antiseptics has had hold alike of laymen and physicians. Not only do these antiseptics not disinfect wounds, but their use has led to a shameful disregard of most of the cardinal principles of wound healing and consequently an untold number of unnecessary infections. The substitution of sulfonamide preparations either as fine crystals in dusting powder (microcrystals) or

ointment in a water soluble base is accomplishing much to remedy this tendency.

It is obvious from what has been said that wounds which by reason of lapse of time may be regarded as infected and those which may be regarded as soiled but which cannot be satisfactorily cleaned should after the primary treatment be left open and managed for healing by second or third intention.

The fire of a clinically infected wound may vary from a flicker to a conflagration, it may readily go out or it may lead to suppuration, great damage of living tissues, septicemia or pyemia. The treatment of infected wounds must necessarily be almost as varied as the nature and character of the infections.

The *care of infected wounds* is not by any means solely a problem of drainage and germicidal therapy. In fact incision should usually be avoided in the presence of lymphangitis and cellulitis unless there is actual suppuration. Except in rare instances in which the swelling in an area of cellulitis imperils the blood supply, it is wiser to devote twenty-four hours to systemic chemotherapy, rest (both general and local) and warm moist dressings locally. If it is then necessary to operate, the chance of spreading the infection is diminished. Prior to actual suppuration it is difficult to justify any incisional measures in the treatment of an infected wound. The price to be paid in the nature of traumatization, necrosis and the opening of new avenues for the spread of the infection is not often warranted.

When suppuration has occurred however, some form of *external drainage* becomes necessary sooner or later in order to avoid the damage of tension, accumulated toxins and spread of the infection. Deciding when to do this must obviously vary with the nature of the infection. In the case of a mild infection when the living tissues are throwing up a barrier of granulation tissue, good beginning to localize it, a non-operative procedure may often be profitably employed for a time before external drainage is established. In such cases when the time does arrive to release the tension of the pus, a small reopening of the wound and gentle irrigation with salt solution or Dakin's solution will often effect a speedy healing. At

the other end of the scale occur the rapidly developing infections and suppurations due to virulent organisms against which the living tissues are unable to set up any effective barrier. The patient has a high fever and becomes sick and toxic his resistance becomes lower and the blood stream may contain organisms. The immediate complete reopening of such a wound is imperative and debridement should be employed until the infection subsides and healthy granulation tissue covers the surface of the wound. Surgical measures such as transfusions intravenous administration of fluids use of chemotherapeutic agents and fixation of the part should not be overlooked. (For the treatment of gas gangrene hemolytic streptococcal gangrene or erysipelas in or around wounds see sections by Meloney and by Christopher.) In the case of tetanus the wound is usually excised or laid wide open and serum and sedatives are administered as advocated in the standard treatises on the subject.

Between the two extremes of the mild and the fulminating infections of wounds there are many grades which consequently demand almost as varied forms of therapy. Strictly speaking it is doubtful if any two infected wounds can be absolutely alike. In most cases therefore a decision as to what should be done can be reached only after a careful study of each individual instance of suppuration as it arises. This means a conscientious effort to evaluate the capabilities of the tissues involved and of the patient as a whole, of weighing carefully the good and the harm of whatever procedure may be contemplated. Between the conservative and the radical procedures modifications must be made to suit the demands of the intervening grades of infected wounds. It may be added that once the decision is made to open an infected wound the general tendency is to be too conservative. While opening is preferable in order to avoid as much as possible the traumatization due to such foreign bodies as gauze drains and tubes. Hot fomentations and irrigations with fluids not harmful to living cells are usually most helpful.

Tetanus and Gas Bacillus Infections—
The question of the use of tetanus antitoxin should arise in connection with the treat-

ment of every traumatic wound. When the physician would not give it to himself or his family in the case of a given wound it is wise for him to say so to the patient or his family in order to share the responsibility of the slight risk involved. In the case of a penetrating or soiled wound received under circumstances that are at all likely to cause the introduction of the tetanus organism the use of antitoxin must be insisted on. This is especially necessary in the case of a gunshot wound or of a puncture wound of the sole of the foot. I well remember as a youngster watching the agonies of a friend who died after stepping on a nail in a barn yard.

The prophylactic dose of tetanus antitoxin for adults is usually 1500 units which may be repeated in seven to ten days if the likelihood of tetanus is very great. In every case the patient's sensitivity to horse serum should be investigated both by questioning him or his family and by making small intracutaneous tests. There is now on the market a bovine tetanus antitoxin to which a patient who is sensitive to horse serum may not be sensitive. When there is sensitivity to the serum to be used it is imperative that the patient be desensitized by means of repeated small injections before the entire amount is given. In some cases of unusual hypersensitivity it is wise to hospitalize the patient during the administration of the antitoxin.

If a patient is found to be sensitive to horse serum it is well to advise him to be immunized later with tetanus toxoid. At present this requires several weeks and is not a suitable means of protecting the patient from an injury already sustained. However the immunity conferred lasts much longer and may be renewed promptly at any subsequent time by a booster dose. Most of the men in the armed services have received tetanus toxoid and for them an additional dose of toxoid should provide ample protection.

A wound suitable for the growth of one species of clostridia is apt to be suitable for the growth of others so that there is no increasing tendency to use a polyvalent serum which is also effective against the common strains of gas bacilli wherever tetanus antitoxin is used. Such prophylaxis is

a valuable routine in the management of wounds resulting from traffic accidents and compound fractures and in all wounds in which there is extensive devitalization of muscle.

Use of Sulfonamides in the Treatment of Wounds—The sulfonamides have been

hitherto with the sulfonamides because the advantage of doing so seemed to be outweighed by the risk of sulfonamide sensitivity.

At present sulfadiazine appears to be the drug of choice for systemic administration and sulfanilamide crystals the most suitable preparation for local application in wounds. It has not been definitely shown that local application improves the results obtained with systemic administration but it affords a prompt and intense sulfonamide effect in the local area. Zintel and his associates have studied the influence of these drugs on wound healing and have shown that as employed in their experiments they do not delay recovery of the tensile strength of the wound.

It cannot be too strongly emphasized that these drugs should not be used to cover careless technique but it is difficult to deny that their use has favored more limited debridements especially in wounds of the hands and face when it is essential to save as much tissue as possible.

Use of Penicillin—The antibacterial substance elaborated by the mold *Penicillium notatum* has been found extremely effective in combating infections caused by the gram-positive cocci, gonococci, meningococci and certain of the clostridia. It is ineffective against the colon bacillus and most of the gram-negative organisms. Its great advantage over the sulfonamides is its extremely low toxicity and its great effectiveness against the staphylococci. Its use in treating hand infections is especially noteworthy but it will undoubtedly prove to have a wide range of usefulness in treating surgical wounds.

Granulating Wounds—It is obviously essential that anyone charged with the responsibility of treating a granulating wound should have clearly in mind what he wishes to accomplish. If secondary closure is desired intensive antibacterial therapy should be given until the wound is macroscopically free from necrosis and exhibits a minor degree of bacterial contamination in smears and cultures of its secretions. This seems the wisest course to follow in preparing granulations for the reception of any kind of skin graft. If the granulating surface is merely incidental to some deep-seated, more impor-

Fig. 18.—A. Skin graft on an intensely devitalized wound. There is no fibrin or growth of epithelium. B. Condition of the same wound after a second round of intensive debridement. Note the coating of fibrin which forms a medium in which new cells grow. Rapid epithelialization has begun.

widely accepted in the treatment of contaminated and infected wounds and their use is so logical that it may be regarded as an established practice likely to be supplanted by newer chemotherapeutic agents but not likely to fall into disuse for any other reason.

Clean wounds, although probably contaminated to a slight extent in most instances have not often been treated prophyl-

tant pathologic process, such as osteomyelitis, it is often most illogical to treat it at the expense of rest and non-traumatization that are clearly indicated for the more important underlying process. The granulations, if not interfered with, will nearly always provide adequate protection to the body against invasion of bacteria, while the principle of rest is adopted in treating the other condition. If, however, the time arrives when there will be no, or very little, sacrifice to deep healing, then efforts to promote epithelization of the granulations by skin grafting or otherwise up to the point of sinus may be begun.

By far the most frequent problem in connection with a granulating wound is simply to get the epithelium to grow over the surface either from the edges or from islands of grafted skin (Fig. 27). Reduced to its simplest terms, the main problem is to have the granulating surface covered with the best possible medium for the growth of epithelial cells. Thus, practically all granulating wounds should be so handled that this medium will form to the best advantage even in the presence of infection, for without any medium the epithelial cells cannot grow.

Dakinization or antiseptic therapy may be so thorough and energetic as to make a granulating surface practically sterile and have a healthy, red, firm appearance; yet no epithelization will occur. The more modern chemotherapeutic agents have largely displaced Dakin's solution in the preparation of granulating areas for skin grafts (Fig. 27). Coarse gauze placed next to the surface may cause bleeding that will interfere with grafting (Fig. 28).

Finally, if the physician proposes to treat a granulating wound intelligently, he must keep constantly in mind the process by which it must eventually heal; he must be willing to change his procedures to meet the demands of the wound. If the process is being held up by the presence of slough, measures must be taken to assist in its separation. If the process is delayed by malnutrition, efforts should be directed to correct the nutritional deficiency. If infection is preventing successful skin grafting, chemotherapeutic agents will probably be required. If epithelization is prevented by an

overgrowth of granulation tissue, the excess tissue may require cauterization with silver nitrate or surgical removal. There are times when moist dressings are helpful and times

Fig 28—A The effect of removing a dry gauze dressing from a granulating wound. Note the bleeding and the removal by the gauze of the delicate fibrin covering the wound. B The effect of removing a vaselined old linen dressing from a granulating wound. Note that there is no bleeding and the delicate layer of fibrin is not disturbed.

when healing seems to be furthered by exposure to air. Gradually, the exact indications for the various forms of treatment are being learned, but there are still times when one must study the individual wound from

dry to dry and direct the treatment by the response observed

SURGICAL INFECTIONS OF THE SKIN AND SUBJACENT TISSUES

Surgical infections of the skin and sub-
 jacent structures include a rather large and
 important group of lesions many of which
 however because of their location and the
 involvement of other structures are consid-
 ered elsewhere in this volume

The skin is ordinarily resistant to infec-
 tion. The superficial layers of cells normally
 harbor numbers of bacteria particularly of
 the staphylococcus group. In the healthy
 person the organisms rarely cause trou-
 ble and wounds heal readily without be-
 coming infected

Infections occur when the resistance
 either local or general is lowered and their
 seriousness depends on the relation between
 the lowered resistance and the virulence of
 the offending organism. A third factor of
 importance in determining the course and
 character of these infections is the relation
 of anatomical structures

Infection of the skin may occur without

any evidence of a preceding wound or it
 may be secondary to an injury with a break
 in the skin. It is quite probable that in all
 cases some trauma has preceded the infec-
 tion although it may amount to nothing
 more than irritation mechanical or chem-
 ical

The lesions considered here are lymphan-
 gitis, furuncle, carbuncle, felon and paron-
 ychia

LYMPHANGITIS

(See section on *Lymphangitis*)

FURUNCLE

(Boil)

Furuncle is a type of infection which
 occurs without any evidence of a pre-ex-
 isting wound. It is apt to be preceded how-
 ever by some irritation such as the rub-
 bing of a stiff collar on the neck, shaving
 with a dull razor or some other mild de-
 gree of trauma and is frequently seen in
 patients during a prolonged illness such as
 typhoid fever. It is especially liable to occur
 in diabetic and nephritic patients. The in-
 fection is caused by a staphylococcus and
 involves a hair follicle or a sebaceous or
 sweat gland. It may occur anywhere on the
 body but has a special predilection for hairy
 surfaces. A series of boils is apt to occur in
 a person whose resisting power is below
 normal as a result of some debilitating dis-
 ease

The bacteria after gaining entrance to
 a hair follicle set up a reaction attended
 with hyperemia and resulting in a migra-
 tion of leucocytes into the infected area.
 Some of the leucocytes are destroyed by
 the toxins present and liquefied forming
 pus. Soon the defensive reaction obtains the
 upper hand and a definite wall of leuko-
 cytes surrounded by a zone of hyperemia is
 formed. The central area of necrotic tissue
 forms a slough (core) which is finally ex-
 truded after which healing takes place by
 granulation. The degree of infiltration is ex-
 tremely variable and depends on the viru-
 lence of the organism and the defensive re-
 action present

Ordinarily boils are not attended by seri-
 ous complications and are not dangerous to
 life. Their seriousness however is depen-
 dent to a great extent on their location. It

is generally known that furuncles on the face and particularly on the upper lip and in the nares are attended with a very high mortality rate. This is due to the fact that there is a communication between the anterior facial vein and the cavernous sinus and that septic material may be conveyed to the latter by a retrograde thrombosis. Metastatic infection may occur from boils in other locations. Osteomyelitis and metastatic abscesses to internal organs have been reported as occurring secondarily to furunculosis.

The average boil starts with a small red elevation which is extremely tender to touch. The area of redness extends gradually and is the seat of throbbing pain. The center becomes white or yellow from necrosis of the skin and finally opens spontaneously unless it is incised. A small amount of pus is discharged and tends to form a crust over the small opening. After several days the necrotic center is discharged and the pain and tenderness disappear gradually. The indurated area remains for a week or more and gradually disappears.

The degree of pain is variable and depends in great deal on the location of the lesion and on the depth and extent of the infiltration. There may be a mild general reaction. Unless great care is exercised in infection of other nearby follicles occurs and a succession of boils results.

Treatment.—Much has been written about the treatment of boils and many different methods have been enthusiastically advocated. Surgical treatment varies from rather radical early incision to extremely conservative treatment. Treatment in the past few years has swung to the conservative side and it is generally considered that boils on the face are more safely handled without incision or trauma of any kind. The admonition *Noli me tangere* seems particularly applicable in these cases as squeezing or otherwise traumatizing boils in any location is fraught with the danger that the protective wall will be broken down and the infection spread.

The application of hot moist dressings, delaying incision until localization and liquefaction have occurred and then resorting to a small crucial incision is probably attended with as good results as with any treatment.

[Softening unguents have some value—Ed.]

The method of introducing phenol into the necrotic center with a toothpick or other instrument probably lessens pain and hastens the separation of the slough. Attention to the general health of the patient is important particularly the appropriate treatment of diabetic or nephritic patients. The use of autogenous vaccines has been attended with success especially in recurring attacks of furunculosis. [Treatment by means of injections of staphylococci toxin is helpful in some cases—Ed.] X-ray treatment especially in the early stage has proved of value in preventing pain and hastening resolution.

CARBUNCLE

A carbuncle like a boil is a reaction of the skin and subcutaneous tissue to the invasion of a staphylococcus but it differs because of the greater virulence of the invading organism. An impaired defensive mechanism and also certain anatomic factors are of etiologic importance. Invasion takes place in advance of the defensive process and necrosis of subcutaneous tissue with liquefaction occurs over a considerable area.

Fibrous trabeculae interspersed with colonies of fat extending up to the skin direct the destructive process in numerous channels. Multiple areas of necrosis of the skin develop and rupture discharging small quantities of pus. A protective wall of edema and leukocytes finally forms surrounded by a zone of hyperemia. The skin presents a honeycombed appearance surrounded by an indurated reddened area corresponding to the zone of edema and leukocytic infiltration. The indurated area is tender and the patient may have moderate fever.

Free drainage is impossible on account of the intensive ramification of channels extending from the small openings deep into the subcutaneous tissues. Necrosis and sloughing are usually quite extensive unless early surgical intervention is practiced.

Carbuncles are often serious and in some instances extremely dangerous to life especially when occurring in persons who are suffering from some debilitating disease such as diabetes and nephritis.

Occasionally lymphangitis with lymphadenitis occurs and rarely invasion of the blood stream with septicaemia and metastatic abscess. Septic thrombophlebitis may occur with fatal outcome. As a general rule however the prognosis is favorable and healing takes place after a considerable period of suffering and disability.

strips. 3 The use of a gridiron incision with out undercutting. There is a growing opinion that conservative measures result in shortening the duration of the treatment, lowering the mortality rate and improving the cosmetic result. These conservative methods include employment of x-ray vaccines, staphylococcal toxoid and various

Fig. 20—Types of incisions for earl nodes. One of the most useful incisions of all is the gridiron incision (A) but with the multiple parallel incisions made transversely a cross the neck instead of longitudinally as shown in the figure. This is particularly desirable when the earl node is in the middle of the back of the neck as it avoids the ugly scars produced by incisions which cross the skin creases.*

Treatment—While it is quite generally agreed that conservative methods are not valid in the treatment of boils many surgeons believe that carbuncles because of the anatomical factor involved require quite early and radical treatment in order to establish proper drainage and prevent extensive sloughing. These surgical procedures vary from simple incision to excision of the entire lesion with the radio-knife or cautery. The most generally accepted methods are as follows: 1 The use of a cruciate incision extending into the zone of induration with undercutting of flaps. 2 The use of parallel incisions with undercutting of skin

typical applications. Sulfathiazole has been recommended in the treatment of both boils and carbuncles but as yet its value has not been determined. It remains to be shown whether or not penicillin may be effective in the treatment of these lesions.

FELON (Whitlow)

A felon is an infection involving the distal anterior portion of the finger. Its course is determined by the anatomy peculiar to this phalanx. The fascia attached to the bone at the epiphyseal line forms a closed

* By permission of Johnson & Johnson

space which is divided into compartments by trabeculae extending from the bone to the skin. These compartments contain columns of fat which are vulnerable to infection. Infection usually introduced through a trivial wound such as the prick of a pin or thorn is directed down the columns of fat to the bone.

It is possible that in some instances the infection is hematogenous in origin. Inflammatory reaction produces edema, swelling and the formation of pus. Since the connective tissue sac is extremely resistant, enormous pressure develops and eventually shuts off the blood supply to the diaphysis with resulting necrosis and osteomyelitis. The epiphysis is not affected as it receives its blood supply above the connective tissue sac.

A sequestrum is formed and in children is usually found free in the resulting abscess. In adults the dead diaphysis is still attached.

Felon is attended with severe throbbing pain and extreme tenderness of the terminal phalanx. The patient may not be aware of having sustained a wound. There is a moderate amount of swelling in the early stage and if neglected there may be a brown edema. When the pressure becomes great enough to involve the nerves the pain may cease. If neglect is carried to this extreme, marked destruction will have taken place. Obviously early diagnosis and incision are highly important in order to prevent the destruction of bone but unfortunately early diagnosis is not always easy. The marked tenderness of the phalanx usually determines the diagnosis. A throbbing pulsation is suggestive.

Although the joint is above the closed fascial space it becomes involved in some cases, possibly by ill advised incisions and tenosynovitis may occasionally occur.

Treatment—The treatment of felon is immediate incision preferably under gas anesthesia as soon as the diagnosis is made. The incision should be placed laterally so that the resulting scar will not interfere with the tactile sense. It should completely open the closed fascial space without extending beyond it.

The hockey stick incision (Koch) is highly satisfactory. It is sometimes necessary to incise both sides in order to secure

adequate drainage. If after adequate incision drainage persists and exuberant granulations form the presence of a sequestrum should be suspected. Unfortunately early x-ray study gives little information as to whether necrosis has taken place.

The wound is held open with petrolatum gauze or gutta serena tissue. The drain should be left in place for two or three days. A hot wet boric acid dressing is usually

Fig. 32—Hockey stick incision of a felon.

helpful. If a sequestrum has formed it must be removed. If all dead bone is removed the wound will heal promptly by granulation.

PARONYCHIA

Paronychia is a common infection and may be extremely troublesome unless it receives prompt surgical treatment. Inoculation takes place through a torn hanging nail or some other slight wound and extends beneath the fold at the lateral border of the nail (paronychia). Slight swelling, pain and tenderness develop and there may be redness of the skin. A small incision parallel to the edge of the nail made at this juncture may dislodge a drop or two of pus and the wound will heal with no further trouble. If neglected the infection follows the path of least resistance and burrows around beneath the eponychium and extends beneath the root of the nail, detaching it from its bed (subungual abscess). Pus may escape beneath the eponychium.

* Koch J. J. M. A. 20

given in divided doses every four hours over the remaining twenty four hours. After twenty four hours the initial dose was reduced by one third and on the third day to one half. This maintenance dose was given for three to five days after clinical cure ensued to prevent relapse. Older children and adults were given similar treatment except that the dose was calculated at 1 Gm. for 20 pounds (9 Kg.) of body weight for twenty four hours. The average sulfanilamide level in the blood of 121 patients determined forty eight hours or more after admission was 5.8 mg. per 100 cc. Vaccines, internal remedies, injections of antiseptics, and applications of contractile collodion outside of the advancing margin have little if any value. Cold boric acid compresses are generally comforting. Simmers and Lewis⁹ believe that the streptococcus antitoxin marks a definite advance in overcoming the disease and reduces its duration 60 per cent and its mortality 30 per cent. Many observers¹⁰ have reported prompt improvement with roentgen therapy. A large percentage of the patients so treated become afebrile in from twelve to twenty four hours. Nightingale and Starr¹¹ in an experience with over 180 cases of erysipelas in children have obtained very encouraging results with ultra violet irradiation.

INFECTIOUS GANGRENE OF THE SKIN AND SUBCUTANEOUS TISSUES

Gangrene of the skin and subcutaneous tissues due to microorganisms may be either acute or chronic. The treatment of the various types differs markedly and a delay in diagnosis results in a delay in instituting the proper treatment. In the acute cases a diagnosis should be made within a few hours but in the chronic case a diagnosis may be safely made within a few days. The diagnosis in acute gangrene most frequently is made largely on the basis of clinical symptoms. In the chronic forms the clinical diagnosis must be fortified by careful bacteriologic studies.

ACUTE GANGRENE

Acute infectious gangrene may be divided into two subgroups of great importance. These differ in so many features that they should not be confused. The first is relatively common namely gas gangrene. The second is relatively rare namely hemolytic streptococcus gangrene.

Gas Gangrene.—Gas gangrene not infrequently develops in a deep punctured or lacerated wound which extends down into the muscle and carries with it such foreign bodies as clothing, missiles, powder or street dirt. It is therefore common in war wounds. A large proportion of the cases of gas gangrene in civil practice follow compound fractures. Occasionally it develops after the amputation of gangrenous lower extremities of a diabetic or arteriosclerotic patient.

Symptoms.—The disease usually begins with an abrupt rise in temperature and pulse rate. There is general malaise, marked prostration and restlessness as well as apprehension. The pulse rate approaches 120 and the temperature 103° to 105° F. There is usually an increase of pain in the wound.

Signs.—Examination of the wound usually reveals swelling and edema with redness and acute tenderness. The skin at the wound margin first becomes red, then dark, then dark and necrotic while the reddened

area away from the margin takes on a yellowish brown or bronzed tint. If the disease spreads extensively in the muscle the gangrene of the skin margin slowly advances but it does not appear in isolated patches away from the margin. Gentle pressure on the margins of the wound will usually produce a sanguinopurulent exudate in which gas bubbles may be seen. A smear made from this exudate will almost invariably reveal numerous large gram positive bacilli. Gentle palpation of the tissues may reveal crepitus. This may not be appreciated in the early stages but after it appears it may advance appreciably from hour to hour. An x-ray film will frequently demonstrate gas in the tissues even before it can be felt. It may also be heard with a stethoscope. To an experienced observer with a keenly discriminating sense of smell there is a characteristic ferid or mousey odor.

Pathology—The spread of the disease is chiefly in the muscles. It may be confined to a single muscle extending from the wound margin up to its origin leaving the neighboring muscles free but usually it spreads up the neighboring groups as well to a varying extent. The muscles become soft mushy and dark red and microscopic sections show fragmentation of the muscle fibers with gas bubbles, large numbers of gram positive bacilli and a paucity of fixed tissue or wandering cells. (See section on Bacteriology of Surgery.)

Etiology—There are four different species of spore-forming anaerobic bacilli of the gas gangrene group which are pathogenic for man and although they rarely occur in pure culture in gangrenous processes they are believed to be able alone to produce the general and local symptoms of gas gangrene and their specific toxins may cause death. The most common of the gas gangrene organisms is *Bacillus aerogenes capulatus* (*Clostridium welchii*). The others are *B. oedematiens* (*C. novyi*), *Libion septique* (*C. oedematis maligni* or *C. septicum*) and *B. sordelli* (*C. sordelli* or *C. oedematoides*).

Occasionally one sees an emphysematous infection in which none of the pathogenic spore-forming bacilli are found. In such cases smears of the exudate show only cocci and gram negative bacilli. Cultures reveal an aerobic streptococci and either aerobic or

anaerobic gram negative bacilli. These infections generally spread much more slowly than do those due to gram positive bacilli.

Treatment—If the signs are unmistakable or if in doubtful cases large gram positive bacilli are numerous in the smear immediate operative intervention is of utmost importance. This procedure should not wait for the cultural determination of the organisms. The wound should be completely excised and all foreign bodies and necrotic tissue should be removed. Individual muscles should be explored and any inactive or devitalized muscle tissue removed. When all the involved muscle that can safely be removed surgically has been excised the wound should be flooded with a creamy suspension of sterile (Du Pont's medicinal grade) zinc peroxide (now distributed by both Merck and Mallinckrodt) in sterile distilled water and then packed lightly with gauze or absorbent cotton soaked in this material. This in turn is covered with a thick layer of cotton soaked in distilled water. The whole dressing is sealed with petrolatum gauze to prevent evaporation. This dressing should be changed daily until the anaerobic organisms have disappeared from the wound. If the disease is diagnosed soon after its development amputation usually is not indicated unless there is a compound fracture. Gas gangrene antiserum should be used in large quantities. Depending on the severity and extent of the infection two or more "therapeutic doses" should be given intravenously as soon as the diagnosis is made and repeated every eight hours until there is definite subsidence of local and general symptoms. If it is not possible to determine by culture what organisms are present a polyvalent serum should be used but if an analysis of the flora of the wound has been made more specific antiserum should be administered in subsequent treatments.

Recently favorable results have been reported from the use of roentgen therapy and also from sulfathiazole in cases of gas gangrene. One hundred roentgens to the affected area twice a day for three days is the advocated dose of x-rays. Sulfathiazole should be given in an initial dose of 4 Gm. and 1.5 Gm. every four hours thereafter until the infection is under control. Its value in these cases has not been clearly demonstrated as

yet. For the present, one would be justified in advocating these forms of treatment only in conjunction with adequate surgical treatment. Recently penicillin has been used with encouraging results but successfully only when given in huge doses of 50 000 or even 100 000 units every two or three hours.

Hemolytic Streptococcus Gangrene.—Since the author's first report in 1924 this infection has been described by several observers. This disease may occur following a deep wound but is more likely to follow a much more trivial injury such as a scratch cut or hypodermic injection. It generally occurs on the extremities but may involve any part of the body. In the earlier literature some of these cases were described as phlegmonous or grogrous erysipels but there are striking differences between the disease and erysipels which will be brought out later.

Symptoms.—The disease is characterized by the sudden onset of pain and swelling at the site of the injury. The temperature generally does not rise to over 101° or 102° F except in rare instances when the illness is ushered in with a chill. Then the temperature may reach 103° or 104° F. On the other hand the pulse rate is rapid frequently approaching 120. Prostration is marked but instead of irritability there is usually marked lassitude. The patient becomes indifferent to his surroundings and has no appreciation of the severity of his illness.

Signs.—Within twenty-four hours the part becomes red, hot, swollen and lumpy and while at first it may be very painful it later becomes numb or anesthetic. The redness spreads rapidly during the first two days and may be very marked but the margins fade out into the normal skin and are not raised as in erysipels. On the second, third or fourth day the pathognomonic sign of the disease appears. This should be watched for in any acute fulminating inflammation. The sign is a dusky coloring of the skin appearing in a small purplish patch with irregular and ill-defined margins. It may be some distance from the portal of entry. It has at first a bluish tinge which makes it distinct from the brilliant redness of the surrounding skin. At the same time a large blister or bulla may appear over this dusky area or somewhere else on the red surface. These

areas may extend very rapidly and changes in them may be seen from hour to hour. In untreated patients about the seventh, eighth or ninth day if the patient survives this necrotic skin becomes more sharply demarcated from the rest of the skin and a little later partial separation takes place along the edges. Metastatic foci may develop in the lungs or joints or elsewhere in the body. Frequent sites for these metastatic lesions are the subcutaneous tissues usually without gangrene. In a few untreated patients the process may come to a standstill about the end of the second week and large plaques of necrotic subcutaneous fat may separate beneath a relatively normal skin. But as a rule if no treatment is given the case goes on to rapidly overwhelming toxemia with septicemia, extensive metastases and death.

Pathology.—This disease is essentially a gangrene of the subcutaneous tissue with secondary gangrene of a part of the overlying skin resulting from thrombosis of the skin arteries which pass through the sloughing subcutaneous fat. The subcutaneous gangrene may extend for a long distance beyond the area of skin gangrene but hardly ever extends down into the muscle or bone unless the original wound carries it to these depths. The blood culture is positive in about half of the cases.

Etiology.—The hemolytic streptococcus is always found on aerobic culture in these cases and in the great majority of cases it may be found in pure culture out in the advancing margin of the subcutaneous necrosis as well as in the blister or bullar fluid. Beyond the limit of the subcutaneous necrosis there is a zone of redness and edema which yields a sterile culture. Later when the gangrene separates other organisms may contaminate the field but usually do not spread widely. It is almost certain that these associated organisms play no part in the development of the disease and that it is in fact a pure hemolytic streptococcus infection. The rapidity of its development and the extensive necrosis which it causes suggest that the peculiar characteristics of the onset of the infection may be due to a hypersensitivity similar to the Schwartzman or to the Arthus phenomenon.

Treatment.—As soon as the diagnosis has

been made, penicillin should be given in doses varying from 20,000 to 30,000 units every three hours. Surgical treatment should not be delayed and the extent of the subsequent skin necrosis will be greatly increased. Contrary to the usual procedure either in erysip-

TABLE 2—DIFFERENTIATION OF CASES OF ACUTE GANGRENE*

Name	Etiology	Symptomatology	Pathology	Treatment
Gas gangrene	Deep wound in muscle. Gram positive spore forming anaerobic rods. Occasionally anaerobic streptococci in association with aerobic or anaerobic gram negative bacilli. Early development of various kinds of associated bacteria.	Sudden onset. Prolonged general symptoms. High fever, rapid pulse, apprehension, irritability. Relatively mild local signs. Limited redness, swelling and edema of skin. Crepitation. Dusky wound margins. Bronzing of skin. Limited gangrene.	Extensive death of muscle. Fibers broken by gas formation. May spread whole length of a single muscle. Exudate loaded with gram positive rods. Relatively few pus cells. Negative chemotaxis for leukocytes.	Prompt operation. Removal of all foreign bodies and dead tissue. Complete debridement of wound. Daily flooding of wound with a water suspension of Du Pont medicinal grade zinc peroxide. Early administration of large quantities of polyvalent or specific serum. Penicillin in large doses. Sulfathiazole or sulfadiazine.
Hemolytic streptococcus gangrene	Superficial wound. Pure culture of hemolytic streptococcus. No other bacteria or late occurrence of a few other species after gangrenous skin has separated.	Sudden onset. Relatively mild general symptoms. Low fever but rapid pulse. Lassitude, indifference, somnolence. Alarming local signs. Extreme redness and edema with faint sharp margins. Irregular dusky areas on second, third or fourth day. Blisters and bullae. Rapidly developing extensive gangrene.	Extensive necrosis of subcutaneous tissues with a wide zone of sterile edema beyond the limits of necrosis. Heavy exudation of fluid and polymorphonuclears at first and later large numbers of clear phagocytes. Bacteria found all through the necrotic subcutaneous fat and in the blisters and bullae. Thrombosis of some of blood vessels to overlying skin, which becomes gangrenous.	Prompt operation. Long incisions to the limits of the subcutaneous necrosis. Release of all tension. Removal of necrotic tissue as soon as possible with a minimum of bleeding. Hot application of moist heat until subsidence of cellulitis. Then Dakin's solution to favor separation of the slough. Penicillin. Sulfanilamide or sulfadiazine. Skin grafting if defect is extensive.
Erysipelas	Superficial wound. Pure culture of hemolytic streptococcus. No associated bacteria.	Sudden onset. Prolonged general symptoms. Chills. High fever. Rapid pulse. Apprehension. Irritability. Slowly but steadily spreading area of redness with little or no swelling and edema. Fading in the center. Sharp raised margins.	Slight swelling and thickening of skin. No edema of subcutaneous fat. Bacteria in and between subcutaneous and not in center of lesion.	No operation. Soak & local application of ultraviolet light. Serum in severe cases. Sulfanilamide or sulfadiazine, if ultraviolet radiation is not used.

* Melaney Surg., Gynec. & Obst. 37

be delayed an hour after the diagnosis has been made. If it is delayed for twenty-four hours after the pathognomonic signs appear, the chances of recovery will be greatly diminished in streptococcus cellulitis of the ordinary kind. Longitudinal incisions should be made at once through the gangrenous area and should extend in both directions just be-

beyond the limits of the subcutaneous necrosis. The effect of these incisions is to relieve tension and to drain at least partially, the involved area. After operation hot water soaks or hot poultices should be used until the cellulitis subsides. This usually requires two or three days. Then Dakin's fluid should be applied by means of tubes or frequently changed compresses to favor the rapid separation of the slough. Each day as much of the slough as can be removed without bleeding should be cut away. Sulfanilamide by mouth in an initial dose of 6 Gm and 1 Gm every four hours thereafter should be given until the infection has come under complete control. Zinc peroxide is not effective in this condition because the extensive slough prevents adequate contact.

Differential Diagnosis—1 illuminating types of gangrene fall either into the gas gangrene group or into the hemolytic streptococcus gangrene group. They should not be confused for in the former the injury is almost always deep and the invasion is largely in the muscular layers with gas formation and crepitation both in the muscles and in the subcutaneous tissues while the skin is relatively free. In hemolytic streptococcus gangrene on the other hand the injury is usually superficial and the spread is almost always in the subcutaneous tissues with early involvement of the skin and without any crepitation. In gas gangrene the general symptoms are alarming and the local signs relatively mild. In hemolytic streptococcus gangrene the local signs are alarming and the general symptoms relatively mild. While both infections are primarily due to specific organisms infection may be rendered more severe by the association of other bacteria. However in the case of gas gangrene these organisms generally gain a foothold at the same time or before the organisms of the gas gangrene group whereas with hemolytic streptococcus gangrene the hemolytic streptococcus is alone responsible for the initiation of the infection and secondary contaminants grow only after there has been a break at the margin of the gangrenous portion of the skin. Stained smears of the exudate in gas gangrene show many gram positive rods while in streptococcus gangrene the exudate contains only gram positive diplococci or short chains.

Hemolytic streptococcus gangrene has been frequently confused with erysipelas which is likewise caused by a hemolytic streptococcus but certain features sharply distinguish them. They may be differentiated by reference to table 2.

CHRONIC GANGRENE

Cases of chronic infectious gangrene may be separated into four important subdivisions. While all of these groups are characterized by some distinctive clinical features it seems certain that in each type the characteristic lesions are produced not by one organism as in the acute cases but by a special combination of two or more organisms. These diseases may therefore be called synergistic infections. They may be conveniently named as follows: (1) postoperative progressive bacterial synergistic gangrene of the abdominal or chest wall (2) gangrenous impetigo (ecthyma) (3) fusospirochetal infection of the skin and (4) melanic infection of the skin.

Postoperative Progressive Bacterial Synergistic Gangrene—One of the most striking examples of chronic gangrene of the skin is that which occasionally follows the drainage of an abscess either in the peritoneal cavity or in the chest.

Symptoms—In the majority of the cases which have been reported the gangrene has followed drainage of a peritoneal abscess. Usually there is very little general reaction manifested either by fever or anemia and the patient remains in fairly good general condition although as the process goes on he is gradually worn down with discouragement and pain. About the end of the first or second week after operation the patient and the doctor both realize that all is not well with the healing of the wound. *The whole region becomes exquisitely tender. This symptom is an outstanding feature of the disease.* At first the wound becomes red, swollen and tender. In a few days the wound margins or the stitch holes develop a circumferential indurated necrotic appearance. The center of activity becomes purplish while the outer zone takes on a brilliant red. Within a few days the purplish areas widen and the part first affected becomes frankly gangrenous. The color of the dead skin changes to a dirty grayish brown and the

surface is dull like suede leather. The purple zone spreads outward into the red and as it does so the skin becomes raised above the normal skin level. The central side of the purple zone toward the gangrene is sharply defined but irregular and crented. On the outer side it fades off into the red zone and flattens to the level of the normal skin. The gangrenous skin remains firmly adherent to the purple zone and becomes undermined at its free margin but there is very little if any undermining of the normal skin. As the process advances the gangrenous skin hquifies on its inner margin leaving exposed a base of granulation which gradually enlarges.

Etiology—In most of the cases reported in the literature only routine bacteriologic studies were made but when careful anaerobes as well as aerobic methods are used a *microaerophilic non hemolytic streptococcus* may be found in pure culture at the periphery of the lesion not only in the red zone but occasionally just beyond it in the relatively normal tissues. In the gangrenous tissue itself this organism is found to be associated with a hemolytic *Staphylococcus aureus*. When the streptococcus or staphylococcus is injected in pure culture into animals no lesion is produced but when half doses of each organism are combined

Fig. 31.—Typical progressive bacterial synergistic gangrene following cesarean my. Note the two areas starting around retention sutures. Firmly adherent suede leather gangrene surrounded by red purple zone with crented inner margin. Doubt red zone may be facing off into normal skin.

Pathology—The lesion is essentially a necrosis of the skin. The destruction of the dermis is not always complete and here and there some deep islands of epithelium from sweat glands or hair follicles may start patches of regenerating skin. In the gangrenous zone all of the tissues are homogeneously necrotic and masses of cocci in clusters and chains may be found. In the purple zone there is edema and a dense infiltration with wandering cells. Here fewer organisms are present and they appear in diplo form and in short chains. In the red zone there is hyperemia and a few diplo cocci.

and injected a gangrenous process usually develops which will spread during the course of three or four days and simulate to a considerable degree the lesion in man. This has been repeatedly confirmed. With the demonstration that these organisms can do something together which they cannot do alone the theory has been advanced that the disease is the result of a synergistic action of the two organisms the non hemolytic microaerophilic streptococcus being the essential organism in the zone of advance and in some way preparing the ground for the gangrenous action of the staphylococcus. The streptococcus is almost certain

derived from the intestinal tract while the staphylococcus may come from the patient's skin or from the air.

Treatment—In most of the reported cases the original wound was partially closed with 'tension' sutures. Such tissue tension in the presence of contamination may have favored the establishment of the infection. This suggests as a prophylactic measure that all skin wounds should be left unsutured when a peritoneal abscess, chronic empyema or lung abscess is drained. The chronicity of this condition has afforded the opportunity of trying to cure it by many methods. Certain of the reports reflect the ingenuity and persistence of surgeons in using all sorts of chemical and serologic agents both generally and locally in the face of a baffling problem. In almost every case conservative methods including local excision of the gangrenous margins have failed to check the advance of this process, but radical removal of the lesion including the outer zone of redness either with the knife or with the cautery, has almost invariably resulted in prompt disappearance of the disease. Sterilized medicinal grade zinc peroxide suspended in distilled water and applied after the excision helps prevent a recurrence of the infection. Under its application granulations soon appear. The defect left by this radical operation may then very quickly be restored by skin grafting. Recently the author has treated two patients systemically with penicillin with prompt and complete subsidence of the inflammation spontaneous separation of the gangrenous margin and progressive healing without the necessity for wide excision.

Gangrenous Impetigo (Ecthyma)—For a good many years reports have appeared in the literature describing a chronic gangrenous disease of the skin appearing in undernourished persons, both young and old who were generally in a low state of nutrition and were frequently suffering from recurrent attacks of dysentery. It has been given many names by dermatologists among them *ecthyma pyoderma gangrenosum*, *impetigo gangrenosa* and *dermatitis gangrenosa*.

Symptoms—There are very few symptoms with the onset of the infection. Crops of vesicles appear which soon become pur-

ulous and then frankly gangrenous. As they progress they become moderately or seriously painful and the patient is conscious of fever and malaise. This condition may last for months or years with exacerbations and remissions. Frequently a crop of small fresh gangrenous lesions may develop after a recurrence of diarrhea or colitis.

Signs—The lesions are usually multiple and show various stages of development, one lesion following another in rather rapid succession. They occur most frequently on the scalp, face and abdomen but may be found on any part of the body. They generally start as small vesicles surrounded by a red zone. The center then becomes dark gangrenous and depressed. The lesion increases in size slightly and occasionally two or three neighboring lesions coalesce but even the coalesced lesions seldom measure more than 1 or 2 cm. in diameter. The disease is contagious and frequently occurs in several members of a family at the same time. Likewise the patient inoculates other areas of his body. As new lesions develop the old ones frequently dry, the necrotic skin comes off as a scale and a scar is left behind. The larger and deeper lesions however may persist for a long time. The gangrenous center then separates at the margin leaving a ring of depressed ulceration from the center of which the gangrenous plaque stands up like a button. If this separates from its base a clean ulcer is left which slowly heals.

Pathology—The necrosis is relatively superficial with a base of granulations infiltrated with wandering cells chiefly of the large mononuclear variety and with gram positive cocci in short chains and masses.

Etiology—The cause of this disease has been variously explained by different authors but several workers have regularly found a hemolytic streptococcus and a staphylococcus in the lesions and have attributed the disease to a synergistic action of these organisms. With these two organisms in combination similar lesions have been produced in animals while pure cultures of either failed to do so.

Treatment—Most authors believe that the majority of these patients will recover if general nutritional measures are instituted and if the usual methods of treating impetigo are continued industriously. Many cases

surface is dull like suede leather. The purple zone spreads outward into the red and as it does so the skin becomes raised above the normal skin level. The central side of the purple zone toward the gangrene is sharply defined but irregular and eroded. On the outer side it fades off into the red zone and flattens to the level of the normal skin. The gangrenous skin remains firmly adherent to the purple zone and becomes undermined at its free margin but there is very little if any undermining of the normal skin. As the process advances the gangrenous skin liquefies on its inner margin leaving exposed a base of granulation which gradually enlarges.

Etiology—In most of the cases reported in the literature only routine bacteriologic studies were made but when careful anaerobic as well as aerobic methods are used a *microaerophilic non hemolytic streptococcus* may be found in pure culture at the periphery of the lesion not only in the red zone but occasionally just beyond it in the relatively normal tissues. In the gangrenous tissue itself this organism is found to be associated with a hemolytic *Staphylococcus aureus*. When the streptococcus or staphylococcus is injected in pure culture into animals no lesion is produced but when half doses of each organism are combined

Fig. 31. Typical progressive bacterial synergistic gangrene following coecotomy. Note the two areas situated around retained sutures. Only a thin, suede-leather gangrene surround led by raised purple zone with eroded inner margin. Bright red zone erodes its free edge off into normal skin.

Pathology—The lesion is essentially a necrosis of the skin. The destruction of the dermis is not always complete and here and there some deep islands of epithelium from sweat glands or hair follicles may start patches of regenerating skin. In the gangrenous zone all of the tissues are homogeneously necrotic and masses of cocci in clusters and chains may be found. In the purple zone there is edema and a dense infiltration with wandering cells. Here fewer organisms are present and they appear in diplo form and in short chains. In the red zone there is hyperemia and a few diplo cocci.

and injected a gangrenous process usually develops which will spread during the course of three or four days and simulate to a considerable degree the lesion in man. This has been repeatedly confirmed. With the demonstration that these organisms can do something together which they cannot do alone the theory has been advanced that the disease is the result of a synergistic action of the two organisms, the non hemolytic microaerophilic streptococcus being the essential organism in the zone of advance and in some way preparing the ground for the gangrenous action of the staphylococcus. The streptococcus is almost certain

INFECTIOUS GANGRENE OF SKIN

derived from the intestinal tract while the staphylococcus may come from the patient's skin or from the air.

Treatment.—In most of the reported cases the original wound was partially closed with 'tension' sutures. Such tissue tension in the presence of contamination may have favored the establishment of the infection. This suggests as a prophylactic measure that all skin wounds should be left unsutured when a purulent abscess, chronic empyema or lung abscess is drained. The chronicity of this condition has afforded the opportunity of trying to cure it by many methods. Certain of the reports reflect the ingenuity and persistence of surgeons in using all sorts of chemical and serologic agents both generally and locally in the face of a baffling problem. In almost every case conservative methods including local excision of the gangrenous margins have failed to check the advance of this process but radical removal of the lesion including the outer zone of redness either with the knife or with the cautery, has almost invariably resulted in prompt disappearance of the disease. Sterilized medicinal grade zinc peroxide suspended in distilled water and applied after the excision helps prevent a recurrence of the infection. Under its application granulations soon appear. The defect left by this radical operation may then very quickly be restored by skin grafting. Recently the author has treated two patients successfully with penicillin with prompt and complete subsidence of the inflammation spontaneous separation of the gangrenous margin and progressive healing without the necessity for wide excision.

Gangrenous Impetigo (Ecthyma).—For a good many years reports have appeared in the literature describing a chronic gangrenous disease of the skin appearing in undernourished persons, both young and old who were generally in a low state of nutrition and were frequently suffering from recurrent attacks of dysentery. It has been given many names by dermatologists among them *ecthyma pyoderma gangrenosum impetigo gangrenosa* and *dermatitis gangrenosa*.

Symptoms.—There are very few symptoms with the onset of the infection. Crop of vesicles appear which soon become pu-

tulous and then frankly gangrenous. As they progress they become moderately or seriously painful and the patient is conscious of fever and malaise. This condition may last for months or years with exacerbations and remissions. Frequently a crop of small fresh gangrenous lesions may develop after a recurrence of diarrhea or colitis.

Signs.—The lesions are usually multiple and show various stages of development, one lesion following another in rather rapid succession. They occur most frequently on the scalp, face and abdomen but may be found on any part of the body. They generally start as small vesicles surrounded by a red zone. The center then becomes dark, gangrenous and depressed. The lesion increases in size slightly, and occasionally two or three neighboring lesions coalesce but even the coalesced lesions seldom measure more than 1 or 2 cm in diameter. The disc is contagious and frequently occurs in several members of a family at the same time. Likewise the patient inoculates other areas of his body. As new lesions develop, the old ones frequently dry, the necrotic skin comes off as a scab and a scar is left behind. The larger and deeper lesions, however, may persist for a long time. The gangrenous center then separates at the margin leaving a ring of depressed ulceration from the center of which the gangrenous plaque stands up like a button. If this separates from its base a clean ulcer is left which slowly heals.

Pathology.—The necrosis is relatively superficial with a base of granulations infiltrated with wandering cells, chiefly of the large mononuclear variety and with gram positive cocci in short chains and masses.

Etiology.—The cause of this disease has been variously explained by different authors but several workers have regularly found a hemolytic streptococcus and a staphylococcus in the lesions and have attributed the disease to a synergistic action of these organisms. With these two organisms in combination similar lesions have

derived from the intestinal tract while the staphylococci may come from the patient's skin or from the air.

Treatment—In most of the reported cases the original wound was partially closed with 'tension' sutures. Such tension in the presence of contamination may have favored the establishment of the infection. This suggests as a prophylactic measure that all skin wounds should be left unsutured when a peritoneal abscess, chronic empyema or lung abscess is drained. The chronicity of this condition has afforded the opportunity of trying to cure it by many methods. Certain of the reports reflect the ingenuity and persistence of surgeons in using all sorts of chemical and serologic agents both generally and locally in the face of a baffling problem. In almost every case conservative methods including local excision of the gangrenous margins have failed to check the advance of this process but radical removal of the lesion including the outer zone of redness, either with the knife or with the cautery, has almost invariably resulted in prompt disappearance of the disease. Sterilized medicinal grade zinc peroxide suspended in distilled water and applied after the excision helps prevent a recurrence of the infection. Under its application granulations soon appear. The defect left by this radical operation may then very quickly be restored by skin grafting. Recently the author has treated two patients systemically with penicillin with prompt and complete subsidence of the inflammation, spontaneous separation of the gangrenous margin and progressive healing without the necessity for wide excision.

Gangrenous Impetigo (Ecthyma)—For a good many years reports have appeared in the literature describing a chronic gangrenous disease of the skin appearing in undernourished persons both young and old who were generally in a low state of nutrition and were frequently suffering from recurrent attacks of dysentery. It has been given many names by dermatologists among them *ecthyma pyoderma gangraenosum*, *impetigo gangraenosa* and *dermatitis gangraenosa*.

Symptoms—There are very few symptoms with the onset of the infection. Crops of vesicles appear which soon become pus-

ulous and then frankly gangrenous. As they progress they become moderately or seriously painful and the patient is conscious of fever and malaise. This condition may last for months or years with exacerbations and remissions. Frequently a crop of small fresh gangrenous lesions may develop after a recurrence of diarrhea or colitis.

Signs—The lesions are usually multiple and show various stages of development one lesion following another in rather rapid succession. They occur most frequently on the scalp, face and abdomen but may be found on any part of the body. They generally start as small vesicles surrounded by a red zone. The center then becomes dark gangrenous and depressed. The lesion increases in size slightly and occasionally two or three neighboring lesions coalesce but even the coalesced lesions seldom measure more than 1 or 2 cm. in diameter. The disease is contagious and frequently occurs in several members of a family at the same time. Likewise the patient inoculates other areas of his body. As new lesions develop the old ones frequently dry, the necrotic skin comes off as a scab and a scar is left behind. The larger and deeper lesions however may persist for a long time. The gangrenous center then separates at the margin leaving a ring of depressed ulceration from the center of which the gangrenous plaque stands up like a button. If this separates from its base a clean ulcer is left which slowly heals.

Pathology—The necrosis is relatively superficial with a base of granulations infiltrated with wandering cells, chiefly of the large mononuclear variety and with granular positive cocci in short chains and masses.

Etiology—The cause of this disease has been variously explained by different authors but several workers have regularly found a hemolytic streptococcus and a staphylococcus in the lesions and have attributed the disease to a synergistic action of these organisms. With these two organisms in combination similar lesions have been produced in animals while pure cultures of either failed to do so.

Treatment—Most authors believe that the majority of these patients will recover if general nutritional measures are instituted and if the usual methods of treating impetigo are continued industriously. Many cases

packed with fine-mesh gauze or absorbent cotton soaked in the zinc peroxide suspension covered with a thick layer of cotton wet with distilled water and then sealed with petrolatum-impregnated gauze to prevent evaporation. This dressing should be changed daily until the infecting organisms have completely disappeared.

Amebic Gangrene—Amebic infection of the skin has been described by a number of authors practicing in regions in which amebic disease is common. In most of the cases which have been reported the involvement of the skin has been secondary to spontaneous or operative drainage of an hepatic abscess. A few cases of infection of the skin have followed some operative procedure on the large intestine. Two observers have described fistulas about the anus due to amebae. The author and his brother have described a lesion of the buttock and scrotum. Gangrenous lesions of the skin attributed to amebae which seemed to rise without any direct connection with an internal focus of the disease have been listed only twice in the recent literature.

Symptoms—In the cases in which a gangrenous lesion of the skin develops secondary to the drainage of a deeper focus there is always a period of days or weeks during which there is no specific change in the wound. Then the drainage tract becomes red, swollen and painful in a manner similar to that in many drained wounds. Fever is not a prominent feature in these cases.

Signs—The edges of the wounds become infiltrated, everted and raised above the surrounding skin which takes on a dark brown color with hyperpigmentation. As the necrosis spreads the center of the lesion remains as an ulcerated surface covered with dark granulations having "a color resembling that of raw beef which has been exposed to the air for some time" (Hemmerger). The surface is covered with foul smelling exudate of thick brownish, blood tinged pus with shreds of necrotic tissue in it.

Pathology—Usually the chief involvement is in the skin and subcutaneous tissue but the muscle may be involved in which case the whole wound becomes necrotic for a considerable depth. In amebic lesions which have no connection with a deep focus

the infection with amebae apparently must be preceded by an established infection with other organisms. This at once suggests the possibility of a symbiotic rather than a specific action. In such a case the infection remains relatively superficial. The spread seems to be in the cutis while the epidermis is involved secondarily and gives way. Gluyus in small droplets may be expressed from the margin of the ulceration. This is said to be quite characteristic of the infection. Amebae may be found in the advancing zone of gangrene.

Pathology—In only one of all the cases reported reviewed by the writer have careful anacrobic as well as aerobic bacteriologic studies been mentioned. The bacterial factor either alone or in symbiosis with the amebae may not have been given the attention which it deserves but in the author's case such studies were made and the conclusion was drawn that amebae may be the essential factor in the production of this type of lesion. It seems to the writer that one or all of the following conditions should obtain before it can be fairly stated that amebae are participating actively in any infection: (1) there should be histologic evidence of the invasion of the tissues by the amebae; (2) they should be found either by smear or culture in the advancing margin of the lesion or (3) the lesion should respond to medical treatment recognized as adequate for amebic disease. The writer believes that the mere presence of amebae on the surface of the lesion or in the exudate is no more evidence of their participation in the infection than the presence of *B. coli*, *B. proteus*, *C. welchii* or any of the other intestinal organisms is evidence of their activity in the tissues about a fecal fistula.

Treatment—In all cases of amebic abscess of the liver, the possibility of skin necrosis after drainage must be kept in mind and precautions taken to avoid it. An attempt should be made to protect the skin wound at the time of operation. A two stage procedure might increase wound resistance to the infection. If a one stage operation is performed there should be complete relaxation of the wound with no attempt to close the skin and subcutaneous tissues by suture. If pathogenic amebae have been found, emetin hydrochloride should be given intri-

synergistic group there is no history of amebic infection or evidence of a deep amebic lesion; no amebae are found either in the stools or in the exudate from the lesion or in the tissues and there is no response to antiamoebic treatment. In the amebic cases there is frequently a history of previous amebic dysentery or a frank deep amebic lesion. Amebae are frequently found in the stools as well as in the exudate from the wound and in the tissues and the lesions may respond promptly, often surprisingly, to emetin and iodoquin treatment. In bacterial synergistic gangrene the lesion is extensive but superficial and develops slowly. It does not invade the muscle and the base of the ulcerated center is composed of active granulations which frequently reveal isolated islands of regenerating epithelium. In the amebic infections the lesion is usually deeper; it develops more rapidly and it may involve the muscle. The granulations have a raw beef appearance and islands of regenerating epithelium are rare. Pressure on the margins produces glairy pus in which the amebae may be found. All the lesions of progressive bacterial synergistic gangrene which have been cultured both aerobically and anaerobically at the time of excision have yielded a microaerophilic non-hemolytic streptococcus in pure culture in the spreading periphery of the lesion while cultures in the zone of gangrene have revealed this organism in association with others. As far as the writer is aware the advancing margin of the amebic lesions has been examined bacteriologically only once and the microaerophilic non-hemolytic streptococcus was not found.

Gangrenous impetigo and fusispirochetal gangrene of the skin are more easily differentiated. The differentiation of the types of chronic infectious gangrene may be conveniently summarized in chart form (Table 3).

INDOLENT ULCERS

(See also Section on Ulcers and Plastic Surgery)

Indolent ulcers are chronic necrotizing lesions with fairly regular contour and with rounded edges without undermining of the skin. The base of the ulcer is grayish yellow and sometimes purplish red and from it exudes a seropurulent material having a characteristic foul odor. These ulcers are most often situated on the lower part of the leg or around the malleoli and are usually surrounded by discolored and indurated skin. They tend to grow larger rather than to heal spontaneously.

Under this classification are considered the following kinds of indolent ulcers: (a) varicose ulcers, (b) ischemic ulcers, (c) trophic ulcers, (d) infectious ulcers and (e) Marjolin's ulcers.

VARICOSE ULCERS

Diseases of the central nervous system such as syringomyelia, transverse myelitis, tumors or injuries of the spinal cord or peripheral nerve disturbances such as neuritis, leprosy, injuries or tumors of nerves and other neurotrophic disturbances are predisposing factors to the development of indolent ulcers on the extremities.

The disturbance in the nervous system must be recognized and the nature of the lesion accurately determined in order that specific medical or surgical treatment can be instituted in addition to the local care of the indolent ulcer. Protection of the extremities from further trauma is vitally important.

Treatment.—General Measures.—All predisposing factors must be sought for and eliminated as completely as possible. Diabetes, if present, must be kept controlled at all times by diet alone or by diet and insulin according to the needs of the individual patient. A well balanced diet with an adequate intake of vitamins is essential. Patients with severe secondary anemia should be given at least one unit of freshly drawn whole blood by transfusion before active treatment of the indolent ulcer is started. Varicose veins should be obliterated by ligation or by the use of sclerosing solutions (sodium morrhuate or sarnen) but only after all signs of local inflammation about the indolent ulcer have disappeared.

Local warmth (50° to 90° F.) is beneficial and hastens the healing of indolent ulcers but the application of uncontrolled heat through the use of a cradle with electric bulbs or an electric heating pad or any other mechanical or electrical heating device is absolutely contraindicated. Such uncontrolled heat increases the local metabolism of tissues and augments the need for oxygen without producing a proportional increase in the supply of arterial blood because of the structural changes in the local blood vessels.

Indolent ulcers should be cleansed frequently with warm water. The affected extremity should be elevated above the level of the heart until the edema has disappeared. This requires several days of complete bed rest. Gauze compresses moistened with warm saline solution should be applied every two hours during the day as long as

the patient is confined to bed. This procedure removes all dried secretions from the ulcer and stimulates the growth of healthy granulation tissue at its base.

Areas of chronic necrosis should be kept dry to inhibit growth of bacteria. Antiseptic powders are much less efficient drying agents than are the aqueous solutions of mercuriochrome or tannic acid (Latimer). The frequent application of 5 per cent aqueous solution of mercuriochrome to these areas will cause the necrotic tissue to mummify. Such sterile scabs or eschars must not be forcefully removed. Spontaneous separation of the eschars can be hastened by meticulous care of the skin of the part and by stimulating the local arterial circulation through active and passive vascular exercises. Several weeks or even months may be required for complete separation of the eschar but as long as no infection is present they can do no harm to the host.

When the patient is ambulatory it is essential to provide adequate support to the tissues of the affected extremity. The supportive dressing described by Gordon is satisfactory. A piece of old linen covered with the desired medicament should be applied directly on the ulcer and covered with a small gauze pad or thin rubber sponge so that uniform but gentle pressure is exerted on the ulcer at all times. The tissues of the entire lower part of the leg should be supported by an elastic bandage (no. 8 Ace bandage 2½ inches wide) or by a properly fitted elastic stocking. Such support should be worn whenever the patient is up and about but must be removed when he goes to bed.

The length of time needed to heal a chronic or indolent ulcer varies according to its size, the local condition of the tissues, the nature of the predisposing causes and the general health of the patient. Many indolent ulcers of the extremities are refractory to all forms of palliative treatment.

Surgical Measures.—Surgical debridement of necrotic tissue in an indolent ulcer must be done with great care but more harm than good result from the procedure. Chemical debridement through the careful use of freshly prepared Dakin's solution on small gauze compresses applied directly to the base of the ulcer is a safer means of removing

ing necrotic tissue. An ulcer which has dense scar tissue at the base or is surrounded by scar tissue can frequently be cured permanently by wide and deep excision which leaves only normal tissue at the base. The defect can be covered immediately or at some later time with an Olher Thiersch type of skin graft.

Analysis of the results following surgical or chemical interruption of the sympathetic innervation to the extremity which is the site of an indolent ulcer has shown that the procedure causes the ulcer to heal quickly but that it rarely remains healed. Palliative measures should always be given a fair trial.

INFECTIOUS ULCERS

Infection is the most frequent exciting factor in the production of indolent ulcers. Practically all ulcers become contaminated with a variety of microorganisms. The bacterial flora of an indolent ulcer usually determines its chronicity and since the advent of sulfonamides and penicillin the specific therapy also depends upon the kind of bacteria present.

Chronic ulceration of the skin due to bacterial synergism has been demonstrated by Melency. The chronic undermining ulcer caused by the microaerophilic streptococci also presents a characteristic clinical picture. Melency has shown that activated zinc peroxide used locally and the sulfonamides given in adequate amounts by mouth offer a satisfactory means of controlling this serious variety of infectious ulcer. An ointment containing zinc and calcium peroxides as introduced by Altmeier is much simpler to use and more effective than the zinc peroxide paste for eradicating the microaerophilic bacteria from indolent ulcers.

Specific infections with spirochetes as in syphilis and yaws and with acid fast bacilli as in tuberculosis and leprosy also give rise to chronic ulcers on the extremities. Systemic diseases of these types must always be considered in the differential diagnosis of indolent ulcers for there is nothing absolutely pathognomonic for any of these lesions. Syphilis and yaws tend to produce punched out ulcers on the extremities while the edges of the indolent ulcers associated with tuberculosis and leprosy tend to be indurated and even undermined. A mixed

bacterial infection is usually present and the local appearance of the ulcer is frequently determined by the kind and the virulence of the invading microorganisms. Specific treatment when it is available must always be given in addition to the local care of the ulcers.

Recently Thompson has presented evidence to show that fungus infection between the toes is a factor in the production of chronic ulceration on the lower part of the leg. It is important to eradicate all traces of epidermophyton infection from the feet of a patient with an indolent ulcer. The tissues of the lower part of the leg have been shown to become highly sensitized to the toxins of the fungi and bacteria. The clinical condition of recurrent cellulitis of the extremities which frequently complicates indolent ulcers may be accounted for on such a basis. The use of autogenous vaccines to desensitize these patients has proved successful in stopping the recurrent attacks of cellulitis. The indolent ulcer then responds to local treatment.

MARJOLIN'S ULCERS

An indolent ulcer which has been present for many years may suddenly undergo cellular changes which convert the innocent ulcer into a lesion which endangers the life

Fig. 31.—Marjolin's ulcer. Squamous cell carcinoma has developed at the edges of an indolent ulcer of many years standing. Note the irregularity of the raised border of the ulcer. Sixty-centimeter amputation together with surgical removal of the inguinal lymph glands was performed.

of the patient. The epithelial cells at the margin of the ulcer begin to grow wildly as a result of the constant irritation from exudates, medicaments or infection and from the continued attempts of the skin to cover

the ulcer by epithelial proliferation and growth. Such malignant degeneration of an indolent ulcer is called Marjolin's ulcer (Fig 34). Whenever the edge of an ulcer is raised or appears rolled, hopes of the tissue should be made and the nature of the cellular changes determined. If malignant changes have taken place in the epithelial cells, it is important to ascertain the exact cell type and the grade of activity of the epithelioma so that definitive treatment can be instituted without further delay. These epitheliomas usually do not extend below the superficial layer of the deep fascia of the leg. As they spread by way of the lymphatic pathways, it becomes important to remove completely the regional lymphatic glands by surgical operation as soon as the malignant nature of the lesion is definitely established. These tumors are very resistant to radiation therapy.

In the early stage of a Marjolin ulcer it is possible to remove the lesion completely by widely excising the skin and underlying fascia. The defect can be covered by a split thickness skin graft. When the epithelioma is far advanced, the only hope for permanent cure lies in amputation of the part with complete removal of all the regional lymph glands.

CHRONIC UNDERMINING ULCER

In 1935 a chronically progressive ulceration of the skin was described as a clinical and bacteriologic entity. It is fortunately rare but is of importance because of the extent of its involvement of the surface of the body, because of its stubborn resistance to the usual forms of treatment and because of the frequently fatal outcome.

Clinical Course.—The disease begins gradually in the vicinity of an incised infected lymph gland in an operative wound associated with the intestinal or the genital

tract or in an accidental wound. The lymph gland group occurs in the neck, axilla or groin. The postoperative type generally follows an operation on the intestine, appendix or genital tract. The third type may occur anywhere on the body surface.

What appears to be an ordinary infection fails to follow the usual course of healing. Improvement which may have been present in the early stages gradually ceases. The skin margins slowly become undermined with liquefaction of the subcutaneous fat and connective tissue and inversion of the margins. There is no gangrene of the skin but as the undermining progresses areas in the neighboring skin may take on a dull red or bluish appearance. It is then found that the undermining has extended beneath these areas and the skin has been thinned out as if it were being liquefied from beneath. After a number of weeks a small opening generally appears in these thin areas. These secondary openings gradually enlarge and may extend until they fuse with the original ulcer or they may leave a bridge of skin in between which becomes epithelialized on its deep surface. In lower abdominal lesions the undermining frequently spreads down toward the groin or toward the pubic region, extending into the vulva, into the scrotum or beneath the crease of the groin into the thigh. In these regions it may burrow deeply, dissecting beneath the muscles and forming deep sinuses into the pelvis. In certain places where the skin is more firmly attached to the deep tissues, such as around the umbilicus or the crest of the thigh, the undermining may stop. Sometimes there are portions of the margin where undermining does not take place and healing may proceed with a new growth of skin. Then instead of progressing steadily the margin of the new epithelium may suddenly stop advancing or may rapidly melt away. Occasionally these ulcers develop on the leg after a minor injury. In such cases there is always some undermining of the skin margins but usually they do not undermine extensively in this region.

Pain is usually moderate but may be excruciating. Fever may rise to 101° and 103° F. daily for a long time or may swing to lower levels. During the period of fever the patient is usually greatly prostrated. In the

course of time the lack of response to treatment frequently brings great discouragement and gradually breaks down the patient's morale. This may reach such a degree that the patient expresses a desire to commit suicide. After months or years of suppuration the lesion may gradually heal spontaneously but if improper treatment is given it usually burrows deeply and causes death either by erosion of a large vessel or by the gradual development of amyloid degeneration of the liver, spleen and kidneys.

Etiology—The essential organism in this infection is a hemolytic streptococcus which prefers an anaerobic environment. Its immediate source is probably either the intestinal tract or the vagina. In many cases it can be obtained only by anaerobic cultiva-

tive treatment however and one that will almost always effect a cure provided the medication can be applied to every part of the wound. This is the daily use of medicinal grade zinc peroxide produced by the Du Pont Chemical Company and distributed by Merck and Mallinckrodt which is a white powder containing about 50 per cent of ZnO and lesser proportions of $ZnCO_3$ and $Zn(OH)_2$. The active ingredient here is the zinc peroxide which provides a very highly oxygenated environment which at first inhibits and then actually kills the organisms in the lesion or modifies their cultural characteristics to such an extent that the infection almost at once ceases to advance and starts to retrogress. The powder—which must be the medicinal grade ac-

Fig. 30.—Chronic undermining ulcer involving pelvis and thigh with deep sinus formation and daughter ulcers with *Vol. gangrene* sacral region and thigh. Note the extensive undermining and the irregular openings in the skin with bridges between them.

tion and is therefore frequently missed with the routine aerobic methods. From some lesions it may be obtained aerobically but it can almost always be demonstrated to grow better anaerobically than aerobically. The organism undoubtedly belongs to the group of anaerobes by predilection of Prevot although he did not describe any hemolytic varieties. The term microaerophilic seems to be preferable.

Treatment—Practically every known form of general and local medication and physical modality has been tried in these cases. There has been some evidence of improvement with the use of maggots and there has been at least one spontaneous recovery (after twenty six months following the use of ultraviolet light). The most effec-

tively generating oxygen when suspended in sterile distilled water—should be sterilized in small quantities in a dry sterilizer at $140^{\circ}C$ for four hours and suspended in its own volume of sterile distilled water just before use. This gives an even creamy suspension which may be applied with the aid of a syringe and catheter to all parts of the ulcerated surface and sinuses. It is essential that the medicine reach every nook and cranny of the infected area for the lesion may spread in any region which is not reached. Any unapproachable regions should be opened widely. The ulcerated portion should be covered with fine-mesh gauze or absorbent cotton soaked in the suspension of zinc peroxide. This in turn is covered with a layer of cotton soaked in distilled water. The whole

region should then be sealed with gauze impregnated with petrolatum or ZnO ointment to prevent evaporation. After twenty-four hours the dressing comes away easily without sticking to the wound. The whole wound should be irrigated with sterile saline solution or distilled water and a fresh suspension applied. When the undermined flaps have become sealed down skin grafts may be applied to cover over the remaining defect.

Sulfanilamide should also be given if the patient can tolerate it. In many cases there is hypersensitivity to this drug. In some of the simpler cases this drug alone may effect a cure but a combination of sulfanilamide by mouth if tolerated with zinc peroxide locally will result in the most rapid healing. Recently in a number of these cases penicillin has been used without benefit.

CYSTS OF THE SKIN AND MUCOUS MEMBRANE

Definition.—A cyst is a cavity either natural or newly formed filled with material which is more or less fluid or pultaceous and surrounded by an investing membrane or capsule which separates it from the surrounding tissues. Cysts of the skin and mucous membrane may be classed as either retention or extravasation cysts. Retention cysts occur as the result of a blocking of the normal outlet. Extravasation cysts are encapsulated collections of fluid not in a pre-existing cavity.

General Considerations.—The majority of all cysts occur about the head and neck where they are unsightly. The removal of all such cysts is to be recommended because

some are likely to become actively infected and suppurate and others though rarely may undergo malignant changes.¹⁴

Much care should be exercised in removing cysts. If during extirpation of such a tumor a remnant of its lining is left within the wound the growth will probably recur. Consequently the old method of transfixing the cyst expelling its contents and pulling away its lining membrane is usually unsatisfactory. Excision of a tumor when acutely inflamed is strictly contraindicated.¹⁴

SCHACCOUS CYSTS

(*Atheroma* *Atheromatous Cyst* *Pseudo-Atheroma* *Retention Cyst* *S. bacerosus* *Tumor* *Stomatoma* *Wen*)

Definition.—A sebaceous cyst is a cystically dilated sebaceous gland.

Etiology.—The cause is obstruction or obliteration of the excretory duct of the gland with retention of its secretions. The obstruction may be due to inspissated glandular secretion or to some extraneous cause. Obliteration of the duct may also be a sequel of inflammation of the gland or may possibly be congenital or traumatic. There is some evidence that a tendency to develop sebaceous cysts may be inherited.

Pathology.—A sebaceous cyst has an outer fibrous wall and an inner wall of squamous epithelium representing the secreting cells of the gland. The contents are cheesy more rarely fluid. They consist of sebum fatty epithelial cells and cholesterol crystals and usually give off a rancid odor.

Symptomatology.—Unless there are complications the only symptom is the presence of a rounded painless swelling on the skin with loss of overlying hair when the cyst is located on the scalp. Frequent complications are inflammation and suppuration of the cyst with ulceration of the overlying skin. A rare complication is malignant degeneration.

the body characteristically in great numbers wherever there is lanugo. They are small sebaceous tumors varying in size from that of a millet seed to that of a cherry.¹¹ These swellings often show a black speck at the apex representing the blocked mouth of the duct otherwise the overlying skin is not discolored unless inflamed. The swelling is doughy or slightly elastic on touch and is easily movable in relation to the underlying structures but the skin is not movable over it. It is of very slow growth. Usually a rancid odor of the contents when it is opened is a point of diagnostic importance.

Prognosis—The prognosis is favorable unless the cyst has undergone malignant change. The development of carcinoma on

cyst does not return. Even after carcinoma thus change recurrences after complete removal of the tumor is rare and metastasis is infrequent.

Treatment—Sebaceous cysts are easily removed under local anesthesia. The overlying skin is first divided the incision being made to correspond with the natural folds of the part. Any redundancy of the skin may be removed with the tumor by an elliptical incision. The sac should be removed intact if possible. If it is ruptured all fragments must be found and removed to insure against recurrence or the development of a fistula. Malignant cysts require a liberal incision through healthy tissue on all sides. A malignant tumor should never be cut into during its removal.¹²

DERMOID CYSTS

(Cuticular Cyst Embryoma Inclusion Cyst Pilsiferous Cyst Sequestration Cyst)

Definition—A dermoid cyst is a benign congenital cyst arising from displaced epithelium and containing derivatives of both epiblast and mesoblast.

Etiology—It arises from the infolding of a skin rudiment in the closure of an embryonic fissure or from other displacement of epithelium in the developmental period.¹³

Pathology—The cyst is unilocular with a capsule and with the wall showing the skin structure more or less complete with the strata in reversed order the horny layer being innermost. One or more of the dermal appendages (sebaceous glands sweat glands and hair follicles) are present. The cyst contains an odorless thick liquid or cheesy mass either whitish or yellowish composed of disintegrated epidermal cells cholesterol crystals sebum and frequently lanugo. A dermoid cyst may contain teeth hair and bone and may shade over into a teratoma.

Symptomatology—On the skin the only symptom is the presence of a smooth rounded pinkish tumor usually small and unobtrusive. On the floor of the mouth a dermoid may displace the tongue upward and backward give a nasal quality to the voice or even make speech indistinct it may interfere with respiration deglutition and mastication or produce enlargement of the submental region and even prognathism.

Fig. 36—Large sebaceous cyst over left eye

a sebaceous cyst case is generally considered rare but the subject should not be dismissed without calling attention to this possibility. Schwalbe reviewed the literature in 1914 and found 43 cases of sebaceous cysts in which carcinoma had developed in the cyst walls. In a more recent report among 236 cases at the Mayo Clinic, Collet found 12 (or 5.1 per cent) in which carcinoma occurred. Bishop¹⁴ of the Steiner Cancer Clinic in Atlanta in a review of 119 cases found carcinoma in 9.2 per cent. Stone and Abbey of the New York Post Graduate Medical School and Hospital reported in 1915 in a series of 683 cases of sebaceous cysts an incidence of carcinoma of 2.2 per cent. If the sac is entirely removed the

Diagnosis—Although congenital dermoid cyst frequently does not manifest itself until adult life. It is found most often at the site of an embryonic fissure or channel and in the midline. It is not usually freely movable being attached at the base to the deep fascia but the skin is normally movable over it. To touch it may be soft and doughy or elastic and fluctuant. Through the mucous membrane it has a whitish appearance. The most frequent site of a dermoid cyst of the mucous membrane is the floor of the mouth. Here it may be *sublingual* lying between the genioglossal and geniohyoid muscles or *submental* separated from the mouth cavity by the genioglossal muscle. A submental dermoid does not follow the movements of deglutition. Roentgen examination may help in the diagnosis if the cyst contains opaque material. The final diagnosis is made on the finding of dermal appendages in the cyst wall and sebum and epidermal derivatives in the contents. Dermoid cysts contain one or more derivatives of the dermis such as hair, teeth and sebaceous material. Dermoids in the floor of the mouth or in the submental and submaxillary regions must be distinguished from ramified cystic hygromas, cysts of the thyroglossal duct, chronic suppurative infections of the submaxillary salivary gland, branchial cysts, lipomas and neurofibromas. The one notable feature which distinguishes a dermoid in these regions from the before mentioned conditions is its *puffy, like or doughy feeling on palpation*.¹³

Prognosis—For dermoid cysts of the skin and mucous membrane the prognosis is favorable if no complications arise. The cyst will not return if the sac is wholly removed. Malignant degeneration (sarcomatous and carcinomatous) occurs occasionally with or without metastasis. It occurs in 19 per cent of the cases of dermoid of the breast. The presence of a round circumscribed subcutaneous lesion of the breast should be suspected as being a dermoid cyst and as potentially malignant. Transillumination may help clinically in distinguishing a cyst from a solid mass.¹²

Treatment—Complete extirpation is the operation of choice. It is important to remove the entire cyst wall. Local field block with 1 per cent novocain is very satisfac-

tory. The incision should follow the natural lines of the skin of the area involved. A dermoid of the floor of the mouth if small may be removed through the mouth if large through an incision parallel to the lower border of the mandible with care not to endanger Wharton's ducts.² When a dermoid cyst is adherent to the bone the periosteal attachment must be removed along with the tumor. Also any cordlike extensions should be removed to effect a cure. When an external sinus is present the incision should include an elliptic portion of the skin around the sinus which facilitates the removal of the tract.¹⁴

EPIDERMOID CYSTS

(*Epithelial Cyst, Implantation Cyst, Post-traumatic Cyst*)

Definition—An epidermoid cyst is a benign cyst arising from displaced epidermic cells.

Etiology—The generally accepted theory is that an epidermoid cyst is traumatic in origin and arises from a fragment of epidermis torn off and driven into the deeper tissues in the course of an injury. For this reason it is often called a *traumatic epithelial cyst of the skin*.¹⁵

Pathology—The cyst is unilocular and may or may not have a fibrous capsule. The cyst wall shows the epidermal structure, more or less complete with the stratum corneum in reversed order, the horny layer being innermost. Dermal structures are absent. The contents are a whitish or grayish cheesy mass made up of disintegrated epidermal cells.

Symptomatology—The only symptom unless the cyst suppurates or makes pressure on surrounding structures is the presence of a smooth rounded painless tumor under the skin.

Diagnosis—Rarely have epidermoid cysts been diagnosed as such but they constitute an important skin lesion that may have annoying and occasionally serious complications. It is significant to note that this topic has been given little if any space in textbooks.¹⁶

The most frequent sites are the palms of the hands, the flexor surfaces of the fingers and the toes, next in frequency are the fore-

the body, characteristically in great numbers wherever there is lanugo. They are small sebaceous tumors varying in size from that of a millet seed to that of a cherry.¹¹ These swellings often show a black speck at the apex representing the blocked mouth of the duct otherwise the overlying skin is not discolored unless inflamed. The swelling is doughy or slightly elastic on touch and is easily movable in relation to the underlying structures but the skin is not movable over it. It is of very slow growth. Usually a rancid odor of the contents when it is opened is a point of diagnostic importance.

Prognosis.—The prognosis is favorable unless the cyst has undergone malignant change. The development of carcinoma on

cyst does not return. Even after carcinomatous change recurrence after complete removal of the tumor is rare and metastasis is infrequent.

Treatment.—Sebaceous cysts are easily removed under local anesthesia. The overlying skin is first divided, the incision being made to correspond with the natural folds of the part. Any redundancy of the skin may be removed with the tumor by an elliptical incision. The sac should be removed intact if possible. If it is ruptured all fragments must be found and removed to insure against recurrence or the development of a fistula. Malignant cysts require a liberal incision through healthy tissue on all sides. A malignant tumor should never be cut into during its removal.¹²

DERMOID CYSTS

(Cuticular Cyst, Embryoma, Inclusion Cyst, Piliferous Cyst, Sequestration Cyst)

Definition.—A dermoid cyst is a benign congenital cyst arising from displaced epithelium and containing derivatives of both epiblast and mesoblast.

Etiology.—It arises from the infolding of a skin rudiment in the closure of an embryonic fissure or from other displacement of epithelium in the developmental period.¹³

Pathology.—The cyst is unilocular with a capsule and with the wall showing the skin structure more or less complete with the strata in reversed order, the horny layer being innermost. One or more of the dermal appendages (sebaceous glands, sweat gland and hair follicles) are present. The cyst contains an odorless thick liquid or cheesy mass either whitish or yellowish composed of disintegrated epidermal cells, cholesterol crystals, sebum and frequently lanugo. A dermoid cyst may contain teeth, hair and bone and may shade over into a teratoma.

Symptomatology.—On the skin the only symptom is the presence of a smooth rounded painless tumor usually small and unobtrusive. On the floor of the mouth a dermoid may displace the tongue upward and backward, give a nasal quality to the voice or even make speech indistinct; it may interfere with respiration, deglutition and mastication or produce enlargement of the submental region and even prognathism.

Fig. 36.—Large sebaceous cyst over left eye.

Diagnosis—Although congenital a dermoid cyst frequently does not manifest itself until adult life. It is found most often at the site of an embryonic fissure or channel and in the midline. It is not usually freely movable, being attached at the base to the deep fascia, but the skin is normally movable over it. To touch it may be soft and doughy or elastic and fluctuant. Through the mucous membrane it has a whitish appearance. The most frequent site of a dermoid cyst of the mucous membrane is the floor of the mouth. Here it may be *sublingual*, lying between the geniohyoid and genoglossal muscles, or *submental*, separated from the mouth cavity by the geniohyoid muscle. A *submental dermoid* does not follow the movements of deglutition. Roentgen examination may help in the diagnosis if the cyst contains opaque material. The final diagnosis is made on the finding of dermal appendages in the cyst wall and sebaceous and epidermal derivatives in the contents. Dermoid cysts contain one or more derivatives of the dermis, such as hair, teeth and sebaceous material. Dermoids in the floor of the mouth or in the submental and submaxillary regions must be distinguished from *ranulas*, cystic hygromas, cysts of the thyroglossal duct, chronic suppurative infections of the submaxillary salivary gland, branchial cysts, lipomas and neurofibromas. The one notable feature which distinguishes a dermoid in these regions from the before mentioned conditions is its *putty like or doughy feeling on palpation*.¹⁵

Prognosis—If a dermoid cyst of the skin and mucous membrane, the prognosis is favorable if no complications arise. The cyst will not return if the sac is wholly removed. Malignant degeneration (carcinomatous and sarcomatous) occurs occasionally with or without metastasis. It occurs in 10 per cent of the cases of dermoid of the breast. The presence of a round circumscribed subcutaneous lesion of the breast should be suspected as being a dermoid cyst and as potentially malignant. Transillumination may help clinically in distinguishing a cyst from a solid mass.¹²

Treatment—Complete extirpation is the operation of choice. It is important to remove the entire cyst wall. Local field block with 1 per cent novocain is very satisfac-

tory. The incision should follow the natural lines of the skin of the area involved. A dermoid of the floor of the mouth if small may be removed through the mouth if large, through an incision parallel to the lower border of the mandible with care not to endanger Wharton's ducts. When a dermoid cyst is adherent to the bone the periosteal attachment must be removed along with the tumor. Also any cordlike extensions should be removed to effect a cure. When an external sinus is present the incision should include an elliptic portion of the skin around the sinus which facilitates the removal of the tract.¹¹

EPIDERMOID CYSTS

(*Lipithelial Cyst*, *Implantation Cyst*, *Post traumatic Cyst*)

Definition—An epidermoid cyst is a benign cyst arising from displaced epidermal cells.

Etiology—The generally accepted theory is that an epidermoid cyst is traumatic in origin and arises from a fragment of epidermis torn off and driven into the deeper tissues in the course of an injury. For this reason it is often called a *traumatic epithelial cyst* of the skin.

Pathology—The cyst is unilocular and may or may not have a fibrous capsule. The cyst wall shows the epidermal structure more or less complete with the strata in reversed order, the *horny layer* being innermost. Dermal structures are absent. The contents are a whitish or grayish cheesy mass made up of disintegrated epidermal cells.

Symptomatology—The only symptom unless the cyst suppurates or makes pressure on surrounding structures is the presence of a smooth rounded painless tumor under the skin.

Diagnosis—Rarely have epidermoid cysts been diagnosed as such but they constitute an important skin lesion that may have annoying and occasionally serious complications. It is significant to note that this topic has been given little if any space in textbooks.¹⁶

The most frequent sites are the palms of the hands, the flexor surfaces of the fingers and the torso, next in frequency are the fore-

head and vertex.³ The cyst is found most often in laborers exposed to injury. A history of injury is not always obtainable since a slight trauma may have been the causative factor and may have occurred years before the manifestation of the cyst. The cyst is freely movable and the overlying skin is unattached and normal in color. It is differentiated from a dermoid cyst which it otherwise resembles by the absence of dermal structures and the presence of epidermoid cellular structures. It is differentiated from a sebaceous cyst though the contents are similar in gross appearance by not having the intense sour odor often associated with sebaceous material. Epidermoid cysts rarely become malignant and seldom become infected. If incompletely removed they tend to recur. An epidermoid cyst on the pulp of the thumb or finger may erode into the phalanx.^{6 10}

Prognosis—The prognosis is favorable unless malignant changes which are rare occur.

Treatment—Radical extirpation before infection has supervened is the ideal treatment. The postoperative reaction is slight.

MUCOUS CYSTS

(Retention Cyst)

Definition—A mucous cyst is a cystically dilated mucous gland.

Etiology—Inflammation of the gland or irrimatism of the orifice of the duct may cause occlusion or obliteration of the excretory duct with retention of the glandular secretions.

Pathology—The cyst may be unicellular or multicellular. The wall is thin and of glandular structure and may be embedded in the surrounding muscular tissue. The contents are a glairy mucus.

Symptomatology—The only symptom is the presence of a painless bluish somewhat translucent protuberance on the mucous membrane.

Diagnosis—A mucous cyst may occur singly or multiple cysts may develop on the mucous surfaces of the lips and cheeks floor of the mouth border of the tongue and vulva. They present rounded tense fairly movable tumors darker in color than the surrounding mucous menl rare and varying

in size from that of a pea to that of a hazel nut always being larger when occurring in the floor of the mouth. Their growth is slow.

A rare condition lately described by Gross is that of recurring myxomatous cutaneous cysts of the fingers and toes which is believed to be a myxomatous degeneration of the derma resulting in a peculiar mucoid change in the connective tissue of the corium this process leading to liquefaction and cyst formation. This type of cyst is apparently not connected with the joint. Lursa or tendon sheath a puzzling pathogenesis. It occurs as a small thin walled cyst on the dorsal aspect of the finger or toe and contains a colorless odorless thin or gelatinous fluid. It is refractory to surgical treatment recurring repeatedly after excision. The best results are secured from x ray or radium therapy.¹²

Prognosis—The prognosis is favorable. Malignant change is unknown or extremely rare.

Treatment—Cure is usually effected by the removal of the wall of the cyst. Occasionally it will be wise to cauterize the cavity with the cautious use of an electric cautery.

BLOOD CYSTS

(*Extravasation Cyst Hematocyst Hemorrhagic Cyst Blood Blister Hemangioma Vascular Nevus*)

Definition—As indicated by the synonyms three different pathologic entities found in the skin and mucous membrane pass under the name of blood cysts. The first is an exudative cyst containing degenerated blood. The second is a cyst of a blood vessel familiarly called a blood blister and appearing usually on the tongue or lip. The third is a blood lake developing in a neoplasm composed of proliferated or hypertrophied blood vessels. (See section on Angioma in the chapter on the Vascular System.)

Etiology—The exudative cyst arises from a bruise with hemorrhage into the subcutaneous tissues forming a hematoma which for some reason fails to become absorbed liquefies and becomes walled in by reticative fibrosis. The blood blister type of cyst has its origin in a varix. The blood

lake' in the congenital vascular tumor is produced by the breaking down of the endothelial elements

Pathology—The exudative or extravasation blood cyst has a thick fibrous wall showing hematinoid crystals in its inner layers. The content is a clear yellow serum. The pathology of the other types of blood cysts mentioned is sufficiently indicated by their definition and etiology.

Symptomatology—Usually the only symptom is the presence of a small tumor generally bluish in color but reddish or purplish if on the mucous membrane. If the tumor is deeply situated the skin is not discolored. A cavernous hemangioma or nevus may be very disfiguring.

Fig. 37—Hemangioma (blood cyst) of the tongue. This tumor gradually became larger over a period of fifteen years. (Courtesy of Dr. B. Shelnire.)

Diagnosis—The diagnosis should not be difficult to make from their appearance alone. If there is doubt it is usually safe to explore a cyst with an aspirating needle. Of the blood cysts found in the mouth or on the inner surface of the lips of infants Shelnire writes: "In addition to this type in infants more complex familial and hereditary vascular tumors may be encountered in the oral vestibule in association with similar tumors on the cutaneous surface and deep blood cysts of the neck."

Prognosis—The prognosis is favorable. There is no fixed tendency to malignant growth or to recurrences when a cyst is removed surgically or treated with radium.

Treatment—The treatment of choice is complete surgical extirpation or exposure to radium therapy, especially the gamma rays. Radium will perhaps give the best cosmetic results. In the treatment of hemangioma of the oral cavity Shelnire¹⁰ has obtained gratifying results particularly in adults by the following method:

An ordinary hypodermic syringe is filled with a 5 per cent solution of sodium morrhuate. The needle is inserted into the cyst and the sodium morrhuate injected until slight distention of the cyst is felt. The needle is then withdrawn and if possible pressure is applied with the finger tips about the cyst to prevent rapid outflow of the injected solution. Moderate pain and swelling of the part follow within a few hours. When properly injected the cyst then has a firm, indurated feel. From two to four injections are required to obliterate the average oral blood cyst.¹⁰ In hemangiomas characterized by extensive metastasis a malignant process may have developed (hemangiosarcoma) and should be treated radically.

Dentigerous cysts and runnels are discussed elsewhere.

NEOPLASMS OF THE SKIN

Neoplasms of the skin can be divided into benign and malignant forms although a sharp distinction between the two may in some cases be impossible either on clinical or histopathologic findings. Only the more common neoplasms especially those requiring surgical treatment will be described here.* Lesions of the mucous membranes including leukoplakia and epithelioma are omitted. Various types of foreign body tumors such as paraffinomas and xanthoma pyogenicum molluscum contagiosum and the verrucae are omitted because they each have an infectious or inflammatory basis. Also various types of xanthomas which have to do with disturbances of metabolism of lipoids. It is important to examine the skin of the entire body as more than one type of cutaneous neoplasm often may be present.

BENIGN NEOPLASMS

Benign neoplasms of the skin include (1) *fibromas* such as single or multiple nodules of dermatofibroma lenticulare (subdermal fibrosis) and multiple pedunculated flaccid and pigmented lesions of neurofibromatosis (von Recklinghausen's disease) (2) *keloids* which are hypertrophic elevated scars either spontaneous or secondary to trauma (3) *neuromas* (4) *lipomas* including adiposis dolorosa (Dercum's disease) (5) *hemangiomas* which are of varying size and depth from the cavernous type to the spider nevus and port wine mark (6) *lymphangiomas* either diffuse or circumscribed often with features of a lymphangiolymphangioma (7) *myomas* which are divided into rhabdomyoma and leiomyoma (8) *chondromas* (9) *osteomas* (10) *dermoids* (11) *rare benign epithelial neoplasms* such as epithelioma adenoides cysticum (Brooke) cylindroma adenoma sebaceum (Pringle)

* For a detailed description of differentiations and features of the other types of neoplasms see the references listed at the end of this section and textbooks on dermatology.

syngangoma and syngangoeptadenoma which do not suggest malignancy clinically although they resemble basal cell epithelioma histologically and (12) *nevi* including the ordinary pigmented mole which may be solitary or multiple and may vary greatly in size and the so called epithelial nevi of which verruca senilis (seborrheic keratosis) is the most common.

Etiologically the benign neoplasm is probably best explained as the result of *Misbildung* (malformation) of the tissue during fetal or postfetal life or as an embryonic rest except chondroma and osteoma which may be attributed to local or generalized metabolic disturbances and keloids and dermatofibroma lenticulare which may result from trauma.

Any benign neoplasm may as the result of repeated trauma or inadequate treatment eventually undergo malignant change although except pigmented nevi the incidence is very low.

Treatment—None of the conditions just mentioned requires surgical treatment except (1) when the neoplasm is situated in an area subject to trauma or irritation (2) when there is pain such as with some keloids of neurofibromatosis or leiomyomas and (3) when cosmetic results are desired as in the case of nevi of various types. Partial removal of pigmented nevi by caustics, fulguration, diathermy or superficial excision ignoring the fact that the roots usually extend to the depth of the hair follicle may frequently lead to malignant melanomas. Keloids may recur following excision in spite of associated radiotherapy. Plastic surgery is indicated in certain cases of superficial angioma especially of the port wine type if the lesion does not respond to radiotherapy, carbon dioxide snow or electrical methods. Benign epidermal neoplasms are relatively resistant to radiotherapy because of their slow growth and when their removal is indicated they should be excised surgically or removed by electrical method.

MALIGNANT NEOPLASMS

Malignant neoplasms of the skin include (1) *epitheliomas* (2) *sarcomas* (3) *lymphoblastomas* (4) rare cases of *endothelioma cutis* and (5) *metastatic lesions* of the skin from neoplasms elsewhere in the body. The

etiology is the same as for cancer elsewhere and remains unknown. Trauma; exposure to actinic rays, including sunlight and radiotherapy; occupation, as in cases of tar cancer; heredity, as in cases of xeroderma pigmentosum, and the Irish or Chénalaine type of skin may be contributory factors. When there is doubt regarding the clinical diagnosis, a specimen for biopsy may be taken without danger of dissemination of the process except in cases of melanoma and Paget's disease of the nipple, in both of which frozen sections should be made at the time of operation. Malignant neoplasms usually occur in the later decades of life, but occasionally they are seen even in childhood.

predominates on the anterior portions of the face and forehead, but it may be found anywhere on the body. Histopathologically, there are strands or a lattice network, or glandular arrangement, or combinations of them, or a solid growth of basal-like cells arising from the basal cells of the epidermis and occasionally from the basal cells of the dermal appendages (Fig. 39, a). Extensive local destruction may result, involving cartilage and bone; when metastasis occurs, however, histologic examination will reveal a transition to a basal-squamous or squamous cell epithelioma. Occasionally, marked deposits of melanin pigment are seen in and between the cells of the tumor. Basal cell

Fig. 39.—a, Senile keratosis with resulting epithelioma, b squamous cell epithelioma, grade I of the face, c, superficial epitheliomatosis showing thread-like border and varying size of lesions on the back, d, melanocarcinoma.

Epithelioma (some prefer the term carcinoma) (Fig. 38 a) includes basal cell epithelioma (*Basalzellenkrebs* or rodent ulcer), basal-squamous cell epithelioma, squamous (prickle) cell epithelioma (Fig. 38, b), and melanoepithelioma (Fig. 38, d) with or without pigment. There are also rare instances of true carcinoma of the dermal appendages or cutaneous metastasis of carcinoma from other organs of the body.

Basal cell epithelioma is a small or large, chronic, slowly progressing, superficial or deep nodule or ulcer, with a rolled, pearly, telangiectatic border, the center of which is usually covered with a crust, removal of which causes bleeding. This type of lesion

epitheliomas may be treated successfully in the great majority of cases by radiotherapy, by excision or by various electrical methods. Roentgen or radium therapy is probably the method of choice in cases of small epitheliomas about the eyelids and canthi. The physician should use the method or combination of methods with which he has become most familiar. Twenty per cent of the neoplasms diagnosed clinically as basal cell epitheliomas prove on microscopic examination to be basal-squamous or squamous cell epitheliomas. They should be excised widely and deeply because both are relatively resistant to radiotherapy; in addition, the basal-squamous type tends to infiltrate the

tissue at the margins in narrow strands of cells without becoming manifest clinically.

Superficial epitheliomatosis (benign erythematoid epithelioma) is characterized by single or multiple lesions (Fig 38 c) that vary in size from a few millimeters to 12 cm or more. These lesions predominate on the trunk and simulate ordinary basal cell epitheliomas except that they have a minute fine thread like border in which case they usually are basal cell epitheliomas when they are eczematoid in character they are basal squamous or squamous cell epitheliomas. Both types of superficial epitheliomatosis are usually resistant to radiotherapy and because of their situation are best treated by surgical excision. Usually skin

cent of cases. Statistics should be based on at least a five year period of observation. Lesions of grades 3 and 4 may lack the clinical features of ordinary epitheliomas and may require histologic differentiation from sarcoma, endothelioma or even benign ulcers. Squamous cell epithelioma of the lip must be distinguished from lesions of primary or tertiary syphilis. Squamous cell epitheliomas of grades 1 and 2 should be radically removed by excision or diathermy and when indicated such treatment should be followed after a years interval by skin grafts of various types if the condition has not recurred. Metastasis to adjacent lymph nodes usually results in cases in which lesions are of grades 3 and 4 so that the prognosis

Fig 39—*a* Basal cell epithelioma *b* squamous cell epithelioma, grade 1 *c* Bowen's disease (epithelioma in situ) *d* squamous cell epithelioma, grade 3

grafting is not necessary because of the laxness of the skin. Superficial epitheliomatosis is frequently confused with benign dermatoses such as lupus erythematosus, psoriasis or tinea circinata.

Squamous cell epitheliomas present as a rule a wider and more indurated border than basal cell epitheliomas. They frequently arise from senile keratoses. Histologically they are graded 1 to 4 by Broders depending on the amount of differentiation of the individual cell, mitosis and pearl formation (Fig 39 *b* and *d*). He found that squamous cell epitheliomas of grade 1 recurred following excision in only 10 per cent of cases whereas for those of grade 4 successful results were obtained in only 10 per

cent of cases. Statistics should be based on at least a five year period of observation. Lesions of grades 3 and 4 may lack the clinical features of ordinary epitheliomas and may require histologic differentiation from sarcoma, endothelioma or even benign ulcers. Squamous cell epithelioma of the lip must be distinguished from lesions of primary or tertiary syphilis. Squamous cell epitheliomas of grades 1 and 2 should be radically removed by excision or diathermy and when indicated such treatment should be followed after a years interval by skin grafts of various types if the condition has not recurred. Metastasis to adjacent lymph nodes usually results in cases in which lesions are of grades 3 and 4 so that the prognosis

is poorer even after surgical excision and subsequent irradiation of the dependent glands. Many physicians and specialists employ intensive radiotherapy in the treatment of squamous cell epitheliomas including in section of radon seeds and needles of radium and administration of filtered roentgen rays in large single or multiple divided doses including the newer technique of daily or alternate daily treatment as by Coutard. It is recognized however that squamous cell epitheliomas are relatively radioresistant.

Melanocytic epitheliomas including melanotic whitlows are characterized by a deep steel blue color with or without radiating lines along lymphatic structures. They frequently develop from small superficial flat deeply

pigmented nevus which have been subject to repeated irritation trauma infection or in complete removal. They should be excised widely in the hope that glandular metastasis and pigmented or non pigmented metastasis elsewhere have not already occurred histologically. If there is evidence of invasion of the lymphatics by the tumor cells the prognosis is serious. When there is evidence of metastasis palliative roentgen therapy is of value in making the patient more comfortable and retarding the progress of the disease but death usually results within a couple of years although exceptionally patients have been known to live for a decade or more after dissemination has occurred. Melanocarcinoma must be distinguished from lesions of subdermal fibrosis with hemorrhage and nevus blau (blue nevus), neither of which presents radiating lines along lymphatic structures. In a blue nevus there usually is the history of onset in early childhood of a blue or blue gray papule or nodule which remains as such throughout life without increase in size. The blue nevus rarely as the result of repeated trauma may become a melanocarcinoma.

The so called precancerous dermatoses should be confined to Bowen's disease to senile arsenic, roentgen ray or radium keratoses to experimental or occupational cancer and to xeroderma pigmentosum. In approximately 20 per cent of the cases studied malignant epitheliomatous change occurs. In cases of xeroderma pigmentosum the epithelioma is usually basal cell in character in all the other conditions mentioned it is usually squamous cell. In the beginning there is an epithelioma *in situ* associated with various phenomena of individual cell keratinization dyskeratosis mitotic and amitotic division of cells and clumping of cells and formation of giant epithelial cells (Fig. 30 c). Rarely as the result of chronic irritation trauma or radiotherapy or even independent of the factors does malignant change develop in benign dermatoses such as lupus erythematosus lupus vulgaris syphilis ulcers sebaceous cyst calcified or not and even psoriasis and lichen planus.

Senile keratoses are to be sharply distinguished from verruca senilis the latter being benign and characterized by a verrucous greasy crust that is readily removed by fri-

tion in contrast to the adherent keratotic crust of senile keratosis or cutaneous horn. Epitheliomas presumably precipitated by arsenic may occur on the trunk and similar lesions of superficial epitheliomatous but clinically they present verrucous keratotic crusted lesions and histologically are usually squamous cell epitheliomas of grades 2 to 4 with individual cell keratinization. All of these conditions call for surgical excision curettization or diathermy. Radiotherapy is contraindicated.

Paget's disease of the nipple is characterized clinically by a persistent sharply circumscribed eczematoid lesion and histologically by the pale-staining Paget cells which are without apparent attachment to adjacent epithelial cells. The writer believes that the lesion of Paget's disease is a peculiar type of epithelioma *in situ* and that there is multicentric origin of the Paget cells from the epidermis and the epithelium of the dermal appendages including the lactiferous ducts. Muir has emphasized the origin of all Paget cells from the lactiferous ducts. In 75 per cent or more of the cases Paget's disease is associated with an underlying carcinoma of the breast so that complete or radical excision of the breast and adjacent lymph nodes is indicated.

Confusion arises among general pathologists and others regarding the differentiation of pseudo epitheliomatous hyperplasia as seen especially in bromoderma ichthyoderma blastomycosis verrucous forms of cutaneous tuberculosis in the borders of chronic leg ulcers and in the tertiary syphiloderms. Familiarity with the histologic changes encountered in the conditions is essential. Marked and deep proliferation of the epidermal ridges even though irregular in outline may be distinguished from true epithelioma by the relative lack of mitotic figures the regular arrangement of cells and the invasion of the infiltrate into epidermal tissue.

Lymphohistioma includes mycosis fungoides which usually begins primarily in the skin and presents indurated plaques of varying size with gyrate borders and the Eczematous. Hodgkin's disease and lymphosarcoma which may occur primarily in the skin but are usually the result of metastasis or of extension from within lymphoid tissue.

VI MILITARY SURGERY*

FOREWORD

This summary of the principles of military surgery is based on the experience of the surgeons of the North African Theater of Operations during the Tunisian Campaign (II Corps) the Campaign in Sicily (7th Army) the Italian Campaign (5th Army) and the Invasion of Southern France (7th Army). Both the 15th Strategic and the 12th Tactical Air Force have been based in this theater. Warfare in the air has spanned the periods of supremacy, decline and disappearance of the *Luftwaffe*.

In this period of nearly two years of active combat the Allied Forces have undertaken five large scale landing operations—North Africa, Sicily, Salerno, Anzio and Southern France. Ground operations have included combat in mountains and river valleys in deserts and rich cultivated fields in large cities and sparsely settled wilderness. Climatic conditions during two summers and winters have exposed the wounded to desert heat and mountain snow to the siroccos of Africa that parch the lips and to the rainy season of the Italian peninsula with flooded rivers and deep mud. Hence the observations recorded and the conclusions drawn are presented as valid for *this geographical region only and for the conditions that prevailed during these two years*.

War is an unending series of specialized situations. In planning only the broadest principles are useful. Directives and experience can only inform the military surgeon; his judgment as an individual at the time and place of an emergency must direct his action.

It is of great importance to recognize the ways that surgery in war may differ from the surgery familiar to civilian life and the reasons that underlie these differences. Only basic principles can be of value in future planning as it is certain that progress in civilian surgery will draw a new baseline of technical procedures before there is need to formulate details in any future war.

MAJOR GENERAL MORRISON C STAYER, USA

THE SCOPE AND NATURE OF MILITARY SURGERY

GENERAL CONSIDERATIONS

The care of the wounded must always be shaped by conditions and circumstances that stem from the exigent nature of war. Even the technical procedures of military surgery are found to differ radically from those of civilian surgery. To understand the

reasons for a departure from principles that appear firmly established by civilian experience it is important to know about some of the conditions that influence surgery in the field. The general impression that surgery in war is entirely molded by concessions to the need for haste and the confusion of caring for overwhelming numbers of patients is erroneous. Military surgery is not to be regarded as a crude departure from accepted

* The source material on which this resume of military surgery is based is the current experience of the surgeons of the Mediterranean Theater. Supporting data are still largely in the form of official reports and only an insignificant portion has been prepared for publication. Assignment of credit where credit is due must await the appearance of articles in the periodical literature under the names of the individual surgeons who have voluntarily called the task of compiling clinical reports to the labor of the actual care of the wounded. Meanwhile I can only express my indebtedness to the surgeons of the theater in offering a preview of their work to the present and future students.

Quantitative expressions of incidence, mortality, etc. have been introduced as percentage values without qualification. This makes for conciseness in contrast to a constant repetition of definite terms such as "about," "approximately," "roughly," and so on. As repeated reference is made to the difficulties that attend exact quantitative statements it is assumed that the designated values will not be taken too literally. When used they are based on analyses of representative samples of significant size and of random selection. They are subject to correction as the total mass of experience is subjected to systematic analysis. Actual numbers can not be given for security reasons.—E.D.C.

surgical standards—'an awful business' as it has been called but as a development of the science of surgery to carry out a specialized and highly significant mission. To keep this development small in the midst of war, when emotional forces so commonly displace scientific motivation is the prime challenge to the military surgeon.

Military surgery is the surgery of trauma encountered in epidemic proportions. Its scope is that of a surgical specialty—the management of wounds and injuries. As a result diagnostic problems are likely to be simple and treatment is immediate and direct. The patients of the military surgeon are young and previously healthy adult males conditioned to a uniform environment and displaying a standard behavior pattern. As a consequence surgical procedures become subject to standardization and a degree of control that at times may mark the surgeon accustomed to the individualistic practice of civilian life.

The violence of the trauma encountered in war with its consequent results on the human body far exceeds that usually encountered in civilian accidents. It is a common error for civilian surgeons to underestimate the destructive nature of flying missiles.

The large number of wounded who require treatment during periods of active combat demands quick decision, efficient organizational teamwork and a time-saving simplification of techniques.

Soldiers wounded in combat must be recovered from remote and oftentimes well-nigh inaccessible positions that are under fire. This introduces a time lag between wounding and surgical treatment that in most instances far exceeds the time lag between injury and treatment in civilian accidents. The lag will vary according to the terrain, the intensity of fire and other uncontrollable factors. It is rarely under four hours in land operations and may be prolonged to several days.

Even after a wounded man is transported by litter and ambulance to a hospital where surgical treatment can be undertaken, evacuation farther to the rear is necessary as soon as his condition permits. The movements of mobile hospitals to keep pace with the front and the necessity of keeping beds

open for newly wounded vary with the tactical situation and may be urgent and unpredictable.

Facilities for surgical treatment are adequate but necessarily demands that they be simple and standardized. The ingenuity of the surgeon is challenged by the necessity to improvise and change his techniques to meet varying situations.

Modern surgical treatment employs many adjuncts to operative techniques that are of inestimable value when used correctly. Chemotherapy, fluid replacement therapy, transfusion of whole blood and the various fractions of blood employed as substitutes, potent anesthetic agents and narcotics are tools that are as important to the military surgeon as his scalpel but equally dangerous to the patient if used without expert precision. To make full use of these and similar measures and at the same time to avoid the dangers that attend their usage is one of the major responsibilities of the surgeon in the forward area.

Phases of Surgical Management.—The ever present necessity for evacuation to the rear divides technical surgical management into first aid measures, initial wound surgery, reparative wound surgery, reconstructive surgery and rehabilitation measures. These phases of surgical management of an individual patient are commonly telescoped in civilian practice into treatment by a single surgeon in one hospital. In time of war this may be strung out across the surface of the globe in a dozen or more hospitals and carried out by as many different surgeons. Surgical procedures must be properly placed in time and space with due regard to the tactical situation on the one hand and to the welfare of the patient on the other.

Unless a surgeon visualizes his position and the function of his hospital in relation to other surgeons and other hospitals, he may become confused in the mission he is to carry out. Although he may perform some needed operation correctly, he is likely to impede the military effort and in addition may do unforeseen harm to a patient if he does an operation at the wrong time or in the wrong place.

The Echelons of Surgery.—The phases of surgical treatment listed above conclude in general with military echelons just as

the placement of the various types of hospitals and consequently the provision of facilities for surgical treatment are determined by the geographic deployment of a military force

First Aid Measures—Within the divisional area surgical management is limited to first aid measures and resuscitation. The wounded are transported by hand litter or jeep to the Aid Station and by litter and ambulance to the Collecting Station and the Clearing Station. Hemorrhage is controlled, splints and dressings are applied, morphia is administered for pain and reconstituted plasma is infused for resuscitation. In addition a booster dose of tetanus toxoid is given and chemotherapy with sulfonamides is initiated if desired.

Wounded men who die in this area are classified as Killed in Action (KIA). Approximately 90 per cent of those killed in action die immediately or at least are not seen alive even by a medical man. The 10 per cent that are seen alive before death usually have severe and multiple wounds (18 wounds per individual) with a predominance of head wounds (20 per cent). About one third of those seen alive die within an hour of being hit. Under these circumstances it is apparent that any attempt to carry surgical treatment above the level of first aid measures in this area would be futile even were it physically possible.

Initial Surgery—At the Divisional Clearing Station the wounded in action (WIA) are sorted into two categories—those that require initial surgical treatment at that point and those that may safely be transported farther to the rear still however to receive their treatment in the Army area.

Situated immediately adjacent to the Clearing Station is a small (50 bed) mobile surgical hospital. This is the farthest point forward at which initial surgical treatment can be properly done. Here certain essentials can be assured: a group of experienced surgeons, anesthetists and operating room personnel, simple but adequate operating room facilities, accommodation of the patients under shelter, nursing care and most important facilities to retain the more seriously wounded for a week or ten days.

Surgical treatment at this point is confined to a small group of wounded who re-

quire treatment for (1) correction of profound physiologic disturbances that immediately endanger life or (2) arrest or prevention of the complication of infection that if allowed to develop or progress may endanger life or lead to grave disability.

In the first category are placed casualties requiring control of continuing hemorrhage, restoration of an adequate effective blood volume, correction of mechanical disturbances of the cardiorespiratory system that directly cripple the functions of the heart and lungs and relief of pressure effects of craniocerebral wounds that threaten the continued function of vital centers. From the clinical standpoint these casualties include (a) continuing hemorrhage uncontrollable by first aid measures, (b) severe shock or hemorrhage, (c) sucking chest wounds or chest injuries producing respiratory distress, (d) head injuries with increased intracranial pressure and (e) maxillofacial wounds with respiratory obstruction.

The second category is subject to indefinite extension from a theoretical point of view; practically it is limited to casualties requiring control of the most fulminating infections of warfare—peritonitis and clostridial myositis (gas gangrene). From the clinical standpoint these casualties include (a) abdominal wounds, (b) suspected gas gangrene, (c) wounds of extremities with impairment of blood supply or those necessitating evacuation of the patient with tourniquet in place, (d) compound fractures of long bones and (e) wounds with extensive muscle damage.

By far the greatest number of wounded are transported five to ten miles farther to the rear to the Evacuation Hospitals. Here initial surgical treatment is carried out and the patient kept until fit for transportation to the base by ambulance, hospital train, hospital ship or airplane ambulance. Employment of air evacuation for wounded before initial surgical treatment is not usual for wherever an advanced landing strip can be established, facilities also can be provided for surgical treatment prior to evacuation. Evacuation by air is so extremely important aid to the surgical management of the wounded that it is a swift and easy method of spanning hundreds of miles of terrain in which roads and rails have been

demolished or are crowded with the transport of supplies.

Reparative Surgery—The general hospitals at the base receive wounded from the hospitals of the forward area for further surgical management. As the initial wound operation is by definition a limited procedure in nearly every case further treatment is required. Soft part wounds purposely left unsutured at the initial operation as a safeguard against infection are closed by suture usually at the time of the first dressing on or after the fourth day. Fractures are accurately reduced and immobilized until bony union takes place. Other procedures designed to prevent or combat wound infection are carried out to shorten convalescence and hasten return to duty or to prepare the wounded for transfer to the Zone of the Interior with minimal disability and deformity.

Reconstructive Surgery—In the Zone of the Interior the facilities of large general hospitals are directed toward final reconstructive surgery. Corrective operations, plastic operations, nerve suture and the fitting of prosthetic appliances are examples of the work that remains to be completed.

Reconditioning—In conjunction with corrective surgical treatment and remedial physiotherapy the final step in the rehabilitation of the wounded soldier is to prepare him for return to duty or for discharge to a useful position in civilian life. General physical training, vocational training and educational and orientation courses are directed toward complete physical and mental rehabilitation.

The Lightly Wounded and Disposition to Duty—Approximately half of those wounded in action who are admitted to hospitals may be classified as lightly wounded. These soldiers require prompt and expert treatment so they may return to combat duty at the earliest possible moment. This service is provided in evacuation hospitals and transfer is made to a convalescent hospital in the Army area from which each soldier is returned directly to his unit. Those that require a longer period of recovery than can be provided in the Army area are evacuated to the Base to rejoin their organizations at a later date or be discharged to a replacement center. Approx-

imately 220 per cent of those admitted to hospitals return to duty without transfer out of the Army area. 102 per cent return to duty from the Base (10 per cent go to non-combat duty). 350 per cent are evacuated to the Zone of the Interior and 29 per cent die. If hospital admissions from injury and disease are included the salvage for duty is much higher—approximately 92 per cent.

Statistics of Military Surgery—A valuation of a numerical expression of morbidity or mortality rates in military surgery requires complete information regarding the derivation of the figures and precise definition of the terms employed. It is impossible to overemphasize this point particularly when an attempt is made to compare the results of the treatment of wounded in one war with those of another or in one theater of operations as contrasted with a different theater or even to compare the results of successive campaigns or battles within the same theater.

The term *battle casualty* is defined in a specified manner for administrative records. Thus the percentage distribution of battle casualties in a certain campaign were:

	Per cent
Killed in action	15.5
Wounded	67.5
Missing	22.5
Died (in hospital)	1.1
Captured	0.4

A hospital however may make a report from a completely different base of reference viz. that of total admissions. These may be divided into battle casualties, injuries and disease. The mortality rate of battle casualties thus becomes based on the number of wounded admitted to hospital.

It is a seeming paradox of war surgery that the farther forward surgical treatment is initiated the higher will be the case mortality rate. It is obvious that the closer a hospital is moved to the front, the fewer will be the number of wounded who die before reaching it and the greater the number who die after admission. A surgical hospital adjacent to the clearing station not only receives wounded early but selectively receives only the most critically wounded. The mortality rate consequently may be 20

to 30 per cent of those admitted. Should such a hospital report a mortality rate of 5 per cent for example it would not be indicative of better surgical treatment but that the hospital is too far behind the front or that poor triage at the clearing station resulted in the admission of less seriously wounded.

The case mortality rate of wounded admitted to evacuation hospitals is 15 to 17 per cent. The mortality rate in a general hospital at the Base is lower (a fraction of 1 per cent) and will vary with the policy that determines the length of time patients are held before transfer to the Zone of the Interior. If this evacuation is rapid the hospitals of the Interior will absorb the delayed deaths from complications and reconstructive operative procedures.

The mortality rate for wounded admitted to a hospital will fluctuate with the type of combat in which the army is engaged. Any tactical situation that disrupts the normal function of the divisional medical service will dilute the stream of wounded that reach the hospital with large numbers of trivially wounded. In the month of April in a certain campaign with a static front the wounded admitted to hospitals numbered 1 775 of whom 89 died (4.6 per cent) in May during a rapid offensive movement 10 220 wounded were admitted to the same hospitals and only 174 (1.7 per cent) died. This was in spite of overcrowding, longer time lag and reinforcement of the hospitals with less experienced surgeons. An analogous tactical situation is presented in the establishment of a beachhead by overwater assault of a task force. Seriously wounded are likely to die on the beach and trivially wounded dilute the stream of those evacuated.

Lack of precision in the definition of the nature of the wound is very misleading. Thus the term abdominal wound may include any injury from a minor abrasion of the abdominal wall to one with extensive destruction of abdominal viscera. Systems of classification rarely provide for the tabulation of multiple wounds frequently listing only the one that is considered most important. It is often impossible however to indicate with certainty that a patient died of peritonitis when at the same time he had

a serious craniocerebral wound and perhaps a compound fracture of the femur in addition.

It is of utmost importance therefore that students of military surgery be cautious in the interpretation of statistics that are said to prove the efficiency of this or that type of treatment or the prowess of any individual surgeon or hospital. At times the mortality rate enables one to make a shrewd guess at the echelon in which the surgical work was carried on—nothing more.

THE PHYSICAL NATURE OF TRAUMA

Effects of High Velocity Missiles.—The anti personnel effectiveness of an explosive projectile is determined by the number, size and the velocity of the fragments of the casement that are set in motion by its burst. The velocity of any single fragment decays during flight as a function of initial velocity, mass and distance of flight. The penetrating power of a flying missile depends not only on mass and velocity but also on the shape which in irregular fragments again varies with the orientation at the time of striking the surface of the target. The wounding power of a missile is more closely a function of its velocity than of its size or shape.

The irregular shape of a high explosive missile and its spinning or rotary movement like the wobbly phases of the flight of a conical bullet may determine the damage inflicted on the tissues immediately adjacent to its pathway. The wider and more extensive destruction of tissues that characterizes a wound inflicted by a high velocity fragment or bullet is attributable to the energy imparted to the tissues with an effect like an internal explosion. As in an explosion the rate at which the energy is delivered or the power that is expended is more important than the total energy absorbed so the destructiveness of a missile is a function of the cube of its velocity.

Particles in the track of a missile are thrown laterally or angularly by imparted energy that passes from particle to particle. The motion of tissue particles varies with the density of the tissue of which they are component parts. Thus a bone may be shattered and the dense fragments may continue as secondary missiles under their

own velocity through less dense muscle. In composite tissues made up of muscle and fascial planes a tearing disruptive action is exerted by the irregular stresses that are developed. In addition a stretching deformity is experienced by adjacent structures as they are distorted by the momentary creation of a cavity that marks the center of the explosive effect. The subatmospheric pressure within this cavity draws in some air a few bubbles of which may remain in the wound.

A missile that penetrates clothing and skin does not simply carry particles of foreign matter into the tissues along its track. As a rod carries a cleaning patch into a rifle barrel or as the 20th Century Limited trails flying papers and dust. By transmitted energy these foreign particles are dispersed widely through the tissues to a considerable distance from the missile tract.

Blast—Characteristic injuries are produced by the waves that are set in motion by detonation of an explosive charge either in air or under water. The effect of the blast wave itself must be differentiated from the concomitant effect of the flash (heat) and gas of the explosion from the injuries sustained by being thrown by the blast and from the independent effects of primary or secondary flying missiles falling masonry, broken gas mains and drowning.

The component of the atmospheric wave that produces injury is the shell of compressed gas that travels in all directions from the center of the explosion with a velocity of 2500 to 3500 feet per second. The velocity decays rapidly and probably is proportionate to the square of the distance from the explosion. The general physical effect of this wave is exerted by body impact and is that of a sudden blow on the chest or abdomen. Lung damage is the prime characteristic of the injury. In addition rupture of the ear drum and occasionally subserosal intestinal hemorrhage or actual rupture of the bowel results. The effects on the central nervous system have been carefully studied because of the confusion with "shell shock" of World War I. The occurrence of blast concussion of the central nervous system that is similar to traumatic concussion has been questioned.

In water with the detonation of a depth

charge a single high pressure wave is set in motion that travels at a velocity of 3000 feet per second. Its effect on an immersed body appears to be caused by the transmission of the pulse of the pressure wave without displacement of tissues. Only air-containing organs (lungs and intestine) are affected and the lesions are similar to those produced by atmospheric blast. The predominant injury in cases of survival is rupture of the intestine.

Acceleration and Deceleration—Violent displacement by the impartment of motion to a static body or sudden stoppage of a rapidly moving body produces trauma that differs from the direct concussion of a blow. This has been studied particularly with regard to its effects on the central nervous system.

The Pattern of Trauma—When a group of individuals are simultaneously subjected to trauma the resulting injuries conform to a general pattern. This has long been recognized in civilian injuries and such entities as miner's elbow and bumper fracture are surgical classics. In warfare the military surgeon must be alert to recognize new patterns so that protective measures may be instituted. Among the patterns peculiar to war may be mentioned "trench foot," "hand mine foot," "high altitude frostbite," "flash burns," "march fracture," "parry fracture" and "desert sore." The name accorded to a pattern type injury may lead to misleading witness "shell shock." Careful search for a pattern by analysis of injuries is important when individuals are exposed to specialized situations as are airplane crews, tank crews, motorcyclists, turret gunners and parachute troops. Safeguards may be introduced by modifying the structure of the vehicle or airplane or adding protective armor.

Causative Agents of the Wounds and Injuries of Warfare—War releases the theme of violence in all possible forms and patterns. Injuries are commonly multiple and in the same individual often times result from more than one type of trauma, e.g., burns and missile, bomb fragments and falling masonry. The relative frequency of different types of flying missiles varies with the tactical nature of the operation—offensive or defensive, land, air, sea or combined assaults, the strength of the position being

attacked or defended the arm or service of the participant and many other considerations. Thus service troops in the rear and in cities sustain wounds from aerial bomb fragments invasion of enemy held territory or crossing of river valleys increases the wounds from booby traps and land mines a strong opposing force of fighter planes adds explosive cannon shells to flak splinters jungle patrols encounter the small caliber rifle bullets of snipers and so on.

Causative agents of war wounds and injuries attributable directly or indirectly to enemy action are listed below. In addition there is a constant and high incidence of accidental injuries that is the inevitable result of having thousands of men exposed day and night to the hazards of assembling operating transporting and repairing heavy machinery explosives and petrol of modern warfare.

- 1 High explosive fragments artillery shells mortar shells airplane cannon anti aircraft flak and rockets and hand and rifle grenades
- 2 Land mines and booby traps high explosive fragments combined with secondary missiles of gravel and earth true shrapnel i.e. round metal balls in certain anti personnel mines
- 3 Bullets machine gun rifle small arms machine pistol etc
- 4 Aerial bombs anti personnel demolition and incendiary types
- 5 Bayonets rare and often accidental
- 6 Flame and flash explosives cordite petrol and phosphorus
- 7 Secondary missiles armor plate plastics concrete masonry etc
- 8 Violent displacement airplane and glider crashes parachute landings being thrown by a blast and tank and other vehicle crashes
- 9 Exposure to elements frostbite trench and immersion foot heat stroke dehydration high altitude frostbite and immersion
- 10 Agents of chemical warfare vesicant irritant, poisonous corrosive and incendiary
- 11 Agents of biological warfare strategic use of endemic disease spread of epidemic disease

Regional Distribution of Wounds from Flying Missiles—Projections of the surface of the body as a silhouette target have been found to yield the following measurements for regional subdivisions

	Per cent
Head and neck	10
Upper extremities	20
Lower extremities	39
Trunk	27

As a vast majority of wounds are from a random distribution of high explosive fragments or machine gun fire it would be expected that the regional distribution of wounds on the body would also be random and would coincide with the foregoing percentages. Several variables come into play two being most important. First statistics on wounds are derived from wounded who survive to reach a hospital and differential immediate lethality may be an important item. Second protective measures such as the steel helmet the use of trenches and armored vehicles interfere with a random hit of the vulnerable target. That the actual statistics do conform in general to the above pattern is shown by the following samples.

(a) 178 014 wounds in the A.E.F. World War I

	Per cent
Head and neck	11
Upper extremities	36
Lower extremities	43
Trunk	8

GENERAL EFFECTS OF TRAUMA

Hemorrhage—Arterial spasm initiated by the violence of the trauma is a potent factor in preventing death by exsanguination. At times the spasm may persist and in itself produce ischemic gangrene or possibly may be a factor in the establishment of infection. Hemorrhage is controlled by a pressure bandage direct clamp and ligature or when other measures fail by a tourniquet. When a limb is hopelessly mangled

so that amputation is inevitable the tourniquet is applied just below the level of proposed amputation and left in place until the operation is completed. The systemic effects of blood loss merge with other factors that reduce the blood volume and result in shock.

Shock—Shock is the disturbance of homeostasis produced by a reduction in the circulating blood volume. The pattern of the reaction as observed clinically is variable and there is no single measurement that records its progress or severity with exactitude. A wounded soldier may walk into a receiving tent showing nothing but slight pallor and yet may be in early shock. From this minimal disturbance the condition extends to that of the widely quoted classic picture of advanced shock sketched by John Collins Warren in 1894:

Reduction in the circulating blood volume is initiated by loss of blood or fluid at the site of injury. Injury includes trauma either mechanical or thermal and infection that appears as a complication. There is no evidence to confirm the hypothesis that increased capillary permeability remote from the site of injury results in the loss of additional plasma until the agonal stage is reached.

Peripheral vasoconstriction goes a long way toward determining the clinical appearance of a patient in shock. The intensity of this reaction varies not only with the volume blood flow but also with the coexistence of certain sympathoadrenal stimuli such as cold, pain, fear and asphyxia. The intensity of the vasoconstriction also varies with age, sex and general condition. Young adult males unweakened by disease react vigorously to loss of blood volume by peripheral vasoconstriction and so provide the dramatic picture of the 'wound shock' of warfare.

Certain bodily changes associated with shock take place only after the circulation becomes inadequate. Each tissue has a limiting point at which it dies from asphyxia. Pathologic changes in tissues and organs generally reflect the length of time during which the circulation was inadequate. Functional impairment or complete and irreversible suppression of function may occur in certain organs, e.g., the kidneys and

delayed death of the entire organism may result despite the fact that other organs have been resuscitated. Shock in itself is not irreversible until agonal changes ensue.

In the treatment of shock, whole blood is the agent of choice. There is no adequate substitute. Portions of blood—plasma, serum or albumin—containing the osmotically active plasma proteins are of value as first aid measure in tactical situations where it is impossible to supply whole blood. They are also of use in injuries characterized by the loss of plasma rather than of whole blood such as burns, massive infection, peritonitis and crush injuries. In these types of trauma a high hematocrit reading is typically found.

Morphine is administered only to relieve pain and thus indirectly treat shock. The dosage should not be large. If an effect is not obtained absorption from the subcutaneous tissues is probably delayed and repeated doses will lead to the sudden absorption of a toxic amount when the circulation is restored. Immediate splinting of the injured part not only relieves pain but minimizes local fluid loss and prevents further tissue damage. Oxygen is administered if the asphyxia resulting from reduced blood flow is being augmented by faulty oxygenation of the blood. The respiratory passages are cleared and any condition crippling the normal action of the heart and lungs is eliminated. Dehydration is corrected by fluid therapy. Body heat is conserved but heroic measures to warm up a shocked patient are dangerous. Vasoconstrictor drugs and stimulants are harmful. The value of extracts of various glands of internal secretion has not been confirmed.

Army hospitals for battle casualties set up a special receiving section known as the 'Shock Ward' or 'Preoperative Ward'. Here wounded men in shock are treated under close supervision until their condition is such that they will withstand necessary surgical treatment. Whole blood is available through a blood bank system that extends back to a blood collecting center in the adjacent Base. Plasma in dry form is provided from the large civilian donor reservoir in the Zone of the Interior.

As a wounded man is resuscitated from shock, an opinion must be formulated as to

when his condition will withstand operation. The goal of shock therapy in the wounded is not only to maintain life but to get the patient into equilibrium so that necessary surgical treatment may be given. It is for this reason that whole blood transfusion is so essential. Movement of the patient anesthetized and operation with its further blood loss place severe demands on the circulatory system and on vital organs that have been partially asphyxiated during the period of shock.

Fat Embolism—Two predominant clinical manifestations of fat embolism follow trauma—pulmonary and cerebral. They appear to occur most frequently following fractures. The pathology and symptomatology are based on minute multiple emboli of droplets of fat. The pulmonary type is likely to be confused with the effects of blast injury on the lungs but usually shows a longer time-lag between injury and onset of symptoms. The cerebral type is confused with the effects of concussion particularly if there is a head wound. It may closely resemble the cortical decerebration of asphyxia.

THE WOUND AND ITS MANAGEMENT

The Wound and Wound Infection—Wounds produced by flying missiles present infinite variations in size, severity, parts of the body that are injured and the effects on the body as a whole. One basic characteristic, however, is common to all wounds—local destruction of tissue with a heavy seeding of microorganisms. For this reason the surgical problem of the wound is inextricably bound with that of wound infection. As all wounds are contaminated, it becomes a matter of academic definition as to when contamination is projected into infection. Considering solely the time factor, this has been arbitrarily set as after the lapse of six hours. As so defined, the vast majority of wounds sustained in land warfare are already infected at the time surgical treatment is initiated.

To understand the nature of wound infection it is necessary to distinguish between bacterial growth limited to the tissues that were devitalized by the injury and invasive infection that starts in the wound and extends to living tissues. The former may be

termed *surface infection with injury necrosis* the latter *invasive infection*.

In the natural process of sequestration of dead from living tissues, bacterial activity plays an active role in proteolysis. A purulent exudate is called forth which blends with liquefying necrotic tissue and literally teems with bacteria. Liquefaction and sequestration of dead muscle may be rapid and the slough pours from the wound as thick and oftentimes malodorous pus. When fibers, tendon or bone have been devitalized either by the direct impact of the missile or by destruction of the blood supply, these tissues are cast off as sloughs or sequestrums. The process is delayed because of their firm attachments to living structures.

Waiting for the sequestration of dead tissues to take place by natural processes is what is called allowing the wound to clean up. Proteolytic bacteria appear to aid this process. Certain oxidizing chemicals hasten the process of liquefaction of dead tissue. The hypochlorite solution of Dakin with a pH adjusted so that injury to living cells is minimized was developed in World War I and has this action. Unfortunately, attention became focused on the bactericidal action of Dakin's solution and it was considered that it was the infection that was being cleaned up."

The bacteria that flourish in dead tissue are predominantly anaerobic in their cultural characteristics and proteolytic in functional activity. A wide variety of clostridial forms find the wound a favorable habitat for growth. In a deep wound with a small aperture to the exterior, gas may be formed under such pressure that it dissects its way along tissue planes to a considerable distance from the wound. Or it may accumulate in a pocket to form a gas abscess. As certain organisms of the mixed flora produce soluble toxins, these may be absorbed and produce fever, malaise and other systemic effects less clearly understood. This type of wound infection—surface infection with injury necrosis—appears in wounds in which surgical treatment is delayed or becomes manifest after incomplete surgical treatment that leaves a residuum of dead and devitalized tissue. Collections of blood or serum in the wound behave like dead

tissue when infected. Evidence of inflammation in surrounding tissues is minimal or absent or is attributable to the injury rather than to the infection.

Invasive infection starting in the wound is usually initiated by a mixture of these same organisms. Its extension is typically by direct continuity along fascial planes and is productive of necrosis of fascia and connective tissue. Edema of the skin and subcutaneous tissue with pain and tenderness marks the course of the underlying phlegmonous extension. Localizing abscesses at times containing gas and malodorous pus are formed. Invasive infection of wounds rarely takes the form of classic lymphangitis with regional infection of lymph nodes. Blood borne metastases are extremely rare. The instant bacteremia when it occurs is usually indicative of septic thrombophlebitis and is uncommon.

The term *anaerobic cellulitis* has been proposed to include both the surface infection with injury, necrosis and the invasive infection of fascial planes and connective tissue. It is not a satisfactory term from the standpoint of either the bacteriologist or the pathologist but it is useful clinically to establish a composite entity that stands in contrast to "gas gangrene" or clostridial myositis.

Certain clostridia that are commonly present in wounds may invade and necrotize living muscles with alarming speed and rapidly fatal result. The term "gas gangrene" is properly limited to this type of invasive infection but because it is a loose and incorrect term it has been replaced by the more specific designation *clostridial myositis*. Certain species particularly *Cl. perfringens* (B. welchii), *Cl. oedematis*, *Cl. ordellii* and *Cl. septicum* (*Vibrio septicum*) have been isolated most frequently in this type of infection. At times they appear to act singly but most frequently they act in association or combination with other organisms. Attempts to correlate the clinical course and local characteristics of the infection with a specific organism provide patterns that are to be considered valid only in the broadest sense. Clinically the "dry" or emphysematous type of gas gangrene appears associated with *Cl. perfringens* as the predominant organism in a majority of cases.

The "wet" or edematous type of infection has been linked with *Cl. oedematis* in many instances and also with *Cl. ordellii*. The difficulties of cultural isolation, pathogenicity tests and species identification superimposed on the almost invariable presence of a mixed bacteriologic flora and the lack of nomenclologic methods for determining resistance or response of the individual subject to specific organisms or strains leave many gaps in the evidence. At present it is better to regard clostridial myositis as one of the broad patterns of wound infection rather than a monobacterial entity.

The onset and course of clostridial myositis may be and usually is rapid and fulminating. Pain is often the first symptom. Symptoms that are attributable to loss of blood volume into the area of progressing infection are grouped as shock and are characteristically those of a reduced volume flow. Symptoms that are attributable to a soluble toxin are less clearly defined but it may be significant that high fever, delirium and rapid pulse appear to be improved by antitoxin administration.

The Initial Wound Operation.—The initial surgical treatment of a wound is commonly referred to as *debridement* according to American usage of the term. It consists of excision of all dead or devitalized tissue. Some confusion exists in the use of this term as French surgeons employ their word *debridement* to describe the opening of the wound by incision so that all recesses are exposed. The actual removal of the dead tissue is the second step of the complete operation and is known by the French as *éclouage* or *parage*. There is a subtle quantitative distinction between these latter two procedures. *éclouage* is a peeling of the inner surface of the wound. *parage* a more radical prying. The term *excision* as used by the French to indicate extirpation of the wound *en bloc* as one would extirpate a malignant tumor and as soundly employed by Boley is avoided by Americans as a theoretical rather than a practical concept.

There is a certain amount of merit in a terminology that recognizes the two steps in the initial surgical treatment of a wound that the French preserve in the terms *debridement* and *parage*. It is a common mis-

take for the beginner to fail to make a free incision of the wound before he attempts extirpation of devitalized tissue. Failure to make a free incision is likely to be combined with excessive excision of skin to gain exposure. This is an error for little if any skin need be excised to prevent infection and excision of skin adds material difficulty to secondary suture.

Foreign bodies that lodge in or near the wound are removed at the time of the initial operation. Preoperative roentgen ray examination is for this reason an important step in surgical management. The significance of a foreign body, particularly a fragment of the missile, resides in the fact that it marks a pocket of the wound that con-

(not packed) with fine meshed gauze which if desired is impregnated with petrolatum. The wound is supported by a firm bandage or a light plaster of paris shell for immobilization.

The principles involved in the no-suture technic of wound management as contrasted with primary suture are debated at the start of every war. Even in the management of civilian injuries they provoke endless discussion. There appears little doubt that a great many war wounds would heal by primary union if they were closed by primary suture. However no surgeon can predict with certainty which wounds will become the site of life endangering invasive infection if closed. Particularly regarding large

Fig 41—Reparative surgery of soft part wound of axilla. A First dressing at base hospital four days following initial debridement and forward evacuation. B Closure of wound by secondary suture with a transposition of skin flap into axilla. C First attempt on leaking site five days after suture, sixteen days after wounding.

tains dead contaminated tissue. Later a foreign body acts as an infected sequestrum that cannot be extruded spontaneously by the body. Foreign bodies are by no means limited to fragments of the missile. Pieces of masonry parts of vehicles and bits of uniform are frequently found in wounds. Fragments of bone completely detached from their blood supply are foreign bodies. Also parts of the body may be displaced by the missile so that an avulsed thumb is found in a deep wound of the thigh or scalp with hair attached in a wound of the neck.

Careful hemostasis is achieved during and at the end of the operation. No sutures are placed in the wound. It is left loosely filled

and complicated wounds no surgeon can exert infallible judgment in the recognition of dead and devitalized tissue unless the wound were to be excised *en bloc* as is a malignant growth with undue sacrifice of normal tissues. Further the approximation of tissues by sutures creates areas of ischemia or actual necrosis. While such areas may be unimportant in a surgical incision made under the safeguards of asepsis they will act as focal points for invasive infection in a wound that is heavily contaminated. The necessity for early transportation of the patient in the postoperative period the interruption of continuity of professional

* Churchill E. D. Ann Surg 120 J. B. Lippincott Co. Publisher

supervision and other considerations inherent in the management of wounded in the field combine with the aforementioned reasons to make the no suture technique an established principle of military surgery.

Surgical Management of Wound Infection—The initial surgical procedure of debridement is carried out in accord with the same principles even though proteolytic infection of the devitalized tissues has established itself clinically. If local invasive infection is present radical incisions are made to expose and remove tissues that are necrotic as a result of the initial trauma or that have been devitalized by the infection. Intra-al plane abscesses are given free drainage. Respect for barriers to infection established by the defense mechanisms of the body has no place in dealing with the type of post-traumatic sepsis under discussion.

Successful treatment of clostridial myositis depends on early diagnosis and prompt radical management. Surgical excision of involved muscles is the basic principle of effective therapy. This may take the form of amputation of an extremity if the limb will be left crippled by the necessary operative treatment or if the vascular integrity has been jeopardized by the initial trauma. Maintenance of blood volume by transfusions is essential. The prophylactic value of polyvalent antitoxin appears negligible but antitoxin is used in the therapy of the established infection.

Reparative Wound Surgery—Leaving a wound open at the end of the initial operation minimizes the likelihood of early infection, particularly of the anaerobic type. It also affords free drainage to surface infection of necrotic tissue if the debridement has been incomplete. These are the advantages of the method. The disadvantages lie in the problem of healing that is imposed. The open wound is exposed to the hazards and complications of air-borne infection and cross infection despite the most rigid dressing techniques. All of the disadvantages of healing by granulation and slow epithelialization are incurred. Disturbance of the surface of the wound by change of dressings promotes infection and febrile reaction and leads to the progressive cachexia of chronic sepsis.

In civil experience this state of affairs

was commonly encountered in the management of osteomyelitis because of the slow sequestration of bone and the large soft tissue defects that complicate the surgical treatment of this disease. To solve the problem Orr introduced the closed plaster method of management which provides immobilization and reduces the complications that arise from frequent dressings. During the Spanish Civil War Trueta adapted the closed plaster method to the management of war wounds reviving a principle that had been utilized by Pirogoff in the Crimean War. Trueta insisted upon meticulous debridement enclosing the wound in plaster of paris and leaving it alone for a number of weeks. If proteolytic infection of residual dead tissue takes place the exudate absorbed by the plaster the compaction and immobilization appears to reduce lymphatic absorption to a minimum. As a consequence the general condition of the patient does not deteriorate. Debridement of dead tissue by bacterial and natural proteolytic action finally is completed and when the cast is removed a clean granulating surface is found.

There seems little doubt that this method is of value in war surgery when enormous numbers of wounded must be cared for by relatively few medical officers. It has been used extensively in Russia and also in England. On the other hand when applied to compound fractures a high price is paid in skeletal deformity as many fractures cannot be held in satisfactory alignment by plaster alone. Incorporation of pins in plaster as proposed by Trueta has been found unsatisfactory when the patient is subject to transportation. When the method is applied to wounds of the soft parts it entails prolonged hospitalization and delay in return of the soldier to duty. The slow healing exaggerates scar formation and late circulatory contracture.

During 1913 in the North African Theater attention was directed toward the old problem of wound closure by secondary suture. In 1914 as the initial surgical treatment of wounds reached a high standard of perfection in the forward area the program of wound closure in the base was extended. When penicillin became available, wound-closing fractures were closed or re-

duced to a size compatible with the completion of natural healing at the time bony union had occurred.

Secondary suture of wounds thus emerged, from a procedure about which there was considerable controversy, to the status of a universally accepted routine. Wound management has become a two stage operation—initial surgical treatment in the forward area at the earliest moment after injury, reparative surgical treatment at the base between the fourth and the tenth day. The original dressing applied after débridement

tion. A notable contrast exists with the Carrel-Dakin ritual of World War I, in which secondary closure was based on quantitative and qualitative bacteriologic examinations of the wound secretions. These laborious and meaningless tests have been totally by-passed in World War II.

How greatly the use of sulfonamides and penicillin has contributed to the success of this development is impossible to say at the present time. The employment of either one or the other or a combination of the two agents has been an integral part of the ini-

Fig 42—Tangential wound of calf producing skin and soft part defect measuring four by five inches. Secondary débridement at base hospital on twelfth day following initial débridement. Immediate split thickness skin graft. First dressing shown five days later (seventeen days after wounding). No chemotherapy for reparative surgery.*

in an evacuation hospital is removed in the operating room of a general hospital several hundred miles to the rear and the operation completed. If the débridement has not been complete, further excision of dead tissue is carried out and closure delayed a few days.

A striking aspect of this development in military surgery is that gross pathologic changes have replaced bacteriologic analysis in forming a judgment relative to the performance of secondary suture. This further confirms the general principle that dead tissue is the key to early wound infec-

tial wound management. Suture of soft part wounds has been successful without either agent at the time of reparative surgical treatment. In complicated wounds, a course of treatment with penicillin has appeared advisable.

A pressure splint undisturbed for eight to ten days and removal of skin sutures as late as the tenth to twelfth day are important to the technics of secondary suture. The procedure should be undertaken only

* Churchill Ann Surg 120 J B Lippincott Co., Publisher

in fixed hospitals where the patient can remain at rest for fifteen days or for a longer period.

The general principle that the time lag between injury and initial surgical treatment is a *detrimental golden period* in wound infections may now be supplemented by recognition of a second critical golden period—that between the initial and the reparative surgical treatment. Fortunately, the time-lag of this second period has been shortened by air transport of the wounded from the forward area to the rear.

Sulfonamides and Penicillin—Two important adjuncts in the surgical management of wounds have been available in World War II—the group of chemotherapeutic agents known as the sulfonamides and the antibiotic substance penicillin. Both are bacteriostatic and to a lesser degree bactericidal. Their effects are known to be highly selective for certain groups, genera, species, or strains of micro-organisms. The sulfonamides are inactivated by the products of tissue necrosis in which para-aminobenzoic acid may or may not be the active inhibitor. Penicillin is rapidly decomposed when applied topically and quickly excreted when administered parenterally. The ability of either agent to permeate dead tissue by diffusion is limited. Their ability to diffuse into body cavities varies.

Both the sulfonamides and penicillin have been used in topical application and systemic medication. They have been used singly and in combination for polybacterial and monobacterial infections in which the bacterial flora has been known, partially known or totally unknown. They have been used both for prevention of infection and for treatment of established infection.

Any attempt to evaluate a subject of such baffling complexity would obviously be premature. It seems likely that a controlled evaluation may never be possible as some or all of these agents become replaced by more potent preparations. For descriptions of the modes and fashions of the usage of these agents reference should be made to the current literature. (See the chapter on Chemotherapy.)

The statement that chemotherapy is not a substitute for surgical treatment in the management of wounds has been made so

frequently that its true significance has been lost in repetition. A restatement of certain basic facts is in order.

1 The key to infection in war wounds appears to be tissue devitalized by the missile and contaminated by a mixed bacterial flora.

2 Blood clots and hematoma when contaminated are comparable to masses of acrotic tissue.

3 Bacterial invasion of living tissues when it occurs is likely to take the form of a necrotizing infection with further tissue destruction oftentimes massive as in clostridial myositis.

4 Dead foreign tendons and bone become detached from living tissue only by a slow process of sequestration. Spontaneous extrusion of sequestered tissues or of foreign bodies of external origin may in fact be impossible.

5 Precise identification of the mixed bacteriologic flora of wounds with significant testing of individual species or strains for human pathogenicity, toxin production and sensitivity to chemotherapeutic or antibiotic agents is a formidable even impossible task. Laboratory techniques are often controversial or inadequate. For this reason the use of sulfonamide and penicillin in the management of wounds must remain empirical at least at present, being based on a knowledge of the properties of these agents supported by clinical experience.

6 The use of sulfonamides and penicillin in military surgery is properly directed toward the extension of the scope of surgery and the achievement of results heretofore considered impossible. They should not be utilized to permit delay in the surgical treatment of wounds or to minimize the completeness of the excision of dead tissue or the surgical drainage of pus.

Anesthesia—In any consideration of anesthesia for military purposes it is necessary to distinguish at once between that carried out in the forward or combat zone on the freshly wounded in the field or evacuation hospital and anesthesia employed in the rear at the station or general hospital and taken usually many days following the initial trauma. In the latter group choices of anesthesia differ in no way from that in civilian practice.

What constitutes good anesthesia for the man who has just been wounded was at one time a matter for considerable controversy. With increasing experience surprisingly general agreement has been achieved. The common views can now be summarized as follows:

1 When long operations (beyond forty minutes) are considered or whenever a patient is in poor general condition or when ever his wounds are such that shock is present or to be anticipated ether anesthesia has proved to be best by a wide margin.

2 Intravenous anesthesia (pentothal) is of great usefulness. It provides for 60 per cent of the anesthesia in the forward zone but for a reasonable degree of safety its use must be restricted to brief (under forty minutes) procedures on able-bodied men in good condition. Procedures where muscular relaxation is not needed. Its use is particularly to be avoided for patients who have suffered considerable blood loss even though their wounds are otherwise trivial. Shock or impending shock contraindicates pentothal. Gas gangrene contraindicates the use of pentothal. Experience has shown that its use is unwise in burned patients in intracranial explorations for operations that involve the airway or in any circumstance in which oxygenation is likely to be impaired.

3 Local anesthesia is occasionally useful for this group of patients but generally speaking the state of mind of the man who has just been wounded is such that general anesthesia is usually the best choice. During periods of heavy action complicated regional blocks are of little use. They are time consuming and require technical experience that is not widely available. The usual multiplicity of wounds in a given individual further minimizes the value of this technique. Two blocks however are widely employed in the forward zone: intercostal nerve block to relieve pain and to effect splinting in injuries to the chest wall and sympathetic blocks to improve blood flow to extremities when interference with the blood supply has occurred.

4 Spinal rectal and chloroform anesthesia have no place in the treatment of the freshly wounded man.

SPECIALIZED PROBLEMS OF REGIONAL SURGERY

Wounds of the Extremities—Fractures—Wounds of the extremities account for approximately 60 per cent of the admissions to the hospital. Between 20 and 30 per cent of extremity wounds are complicated by a compound fracture. In hits from high velocity missiles the bone may be badly shattered and comminuted often with extensive defects of substance. The detailed management of fractures is in accord with principles established in civilian practice with necessary adaptations of the timing of procedures to the need for evacuation of the patient.

First aid splinting in the field brings the patient to a hospital for initial surgical treatment. Definitive reduction and fixation of the fracture is not attempted at the forward hospital but attention is directed toward the prevention of infection by surgical treatment of soft part wounds. The extremity is then immobilized by a method that has been found suitable for transportation to the base. At a fixed hospital in the base definitive reduction and fixation is accomplished and the patient is held until bony union takes place. Thus the management of a compound fracture is divided into phases: first aid splinting in the field; debridement and transportation splinting in the forward area; correction of the deformity with achievement of wound healing and bony union at the base; late corrective surgical treatment (bone grafting, osteotomy, etc.) in the Zone of the Interior.

Vascular Injuries—It has been estimated that in 1 in every 600 cases of wounds of the extremities an injury to a major vascular trunk independent of other damage jeopardizes the integrity of the limb. Many variables aside from the usually considered anatomical site of the vascular interruption may play a part in determining whether ischemic gangrene results or the level at which amputation is necessary. Some of the variables of the initial injury are as follows: severance or thrombosis of the accompanying vein; concussion or division of nerve trunks; the extent and character of the soft part wound in association with the vascular injury; the presence or absence of skeletal injury or other wounds in the same extremity; the severity and duration of the reduc-

tion in cardiac output during the phase of shock, environmental temperature and the pre existing peripheral vascular state of the individual patient. An all important variable in determining the outcome is the extent and nature of any complicating infection that may develop in particular clostridial myositis.

Therapy includes a wide range of procedures, no single one of which is curative. The selection of therapeutic measures and the sequence in which they are applied vary greatly from case to case. Procedures that have been recommended and that experience has shown to be helpful are: double ligation with complete division of the artery, ligation of the companion vein, novocain block of the sympathetic system, sympathetic ganglionectomy, maintenance of a cool environmental temperature, establishment of a normal cardiac output and oxygen carrying capacity of the blood, a dependent position of the extremity and administration of certain vasodilator drugs. Reconstruction of the artery only rarely is feasible but should be carried out with the vitallium tube technique when practicable.

Principles that govern the management of arterial aneurysms, arteriovenous fistulas and pulsating hematomas, all of which are encountered with considerable frequency in war surgery, are identical with those formulated by civilian experience.

Amputations—Amputation of an extremity is a procedure intimately linked with the evolution of surgery and the history of the battlefield. There are three major reasons for amputation—a hopelessly mangled limb, infection and vascular insufficiency. Many amputations are merely completions of traumatic amputations. In World War II the immediate effects of trauma have been found to necessitate amputation in 64 per cent infection in 13 per cent vascular insufficiency in 20 per cent and a combination of vascular insufficiency and infection in 3 per cent of a series of surviving patients. Infection thus played a role in the decision to amputate in 10 per cent.

The technical aspects of amputation have been standardized throughout the Army and closely coordinated with the program of rehabilitation and the fitting of prosthetic appliances.

Peripheral Nerves—Peripheral nerve palsy may result from the concussive effects of a missile or anatomical severance of a nerve. In the former function usually returns within a few weeks. The management of direct nerve injury remains one of the least satisfactory procedures in the field of military surgery.

Suture of a divided nerve at the time of initial surgical treatment of a wound has been held ill advised although from the standpoint of nerve regeneration this would appear to be the ideal time. It is generally considered that nerve repair requires aseptic healing and perfect hemostasis. Neither of these conditions can be achieved in a significant number of complicated wounds. Degenerative changes in the nerve trunk secondary to high velocity penetration may not be immediately apparent. The gross changes are necessary to guide the surgeon in the resection of the traumatized ends of the nerve as a preliminary step to suture.

The great majority of patients with nerve injuries in World War II will be subjected to delayed surgical repair—after the healing of the wound. The results will admittedly leave much to be desired.

Joints—Suppuration with its disastrous consequences is likely to develop in the presence of bone or cartilage injury. Early wide arthrotomy with precise debridement of soft parts, bone and cartilage is recommended. The joint cavity is irrigated with normal saline solution and penicillin is instilled. The objective is a closed joint cavity obtained by suture of the synovial membrane or repair of a capsular defect by fasciae or soft part flap. The skin is left unsutured and the joints above and below are immobilized. For example, an injured knee joint is splinted by a hip spica.

Cranio-cerebral Wounds—About 6 per cent of the men wounded in action and admitted to a hospital have a head wound as the major injury. There is a high immediate mortality on the battlefield from this cause; it has been estimated that 40 per cent of all men killed in action have wounds of the head and 25 per cent have only head wounds.

The pressure effects that constitute such an important problem in the management of closed head injuries are far less frequent in

the penetrating wounds of the head that are encountered in war.

Cranio-cerebral wounds form a notable exception to the general principle that wounds should be left open after the initial operation. For this reason, the primary operation must be the definitive one, with complete removal of devitalized tissue, driven fragments of bone and the missile itself, if

large and accessible through the wound. Debridement is followed by closure of the dura with a fascial graft, if necessary, and suture of the scalp. The operation requires specialized skill and equipment and, as a rule, is undertaken in an evacuation hospital.

The reason that craniocerebral wounds are closed primarily is found in the disastrous sequelae of deep infection within the brain. Edema and swelling cause extrusion of brain substance through an open defect, with the formation of a self-strangulating fungus. Spreading cerebritis and meningitis may find origin in the extruded portion. *Even in late cases, with established infection in the devitalized brain substance, large defects in supporting structures must be avoided.*

Maxillofacial Wounds.—Mutilating wounds of the face and jaws are the most dreaded of war injuries. Early expert management can greatly reduce the ultimate disfigurement and functional disturbance. The incidence is not great, approximately 2.5 per cent of the wounded admitted to the hospital having maxillofacial injuries, many of these of slight consequence.

First-aid measures maintain a clear airway to prevent suffocation. Tracheostomy may be necessary. Surgical management is first directed toward reduction and fixation of osseous deformities, with particular attention to re-establishment of normal dental occlusion.

The soft part injuries are a specialized problem. The tissues of the face tend to retract widely because of their heavy intrinsic musculature. Compounding of the buccal cavity makes some degree of infection inevitable, although life-endangering infection is unusual because of the abundant blood supply. This combination of retraction and fibrosis from infection appears more important in the production of disfigurement than tissue loss caused by the missile. Suture of these wounds is therefore undertaken at the time of the initial surgical treatment. Moist pressure dressings, drainage of dependent areas in anticipation of sepsis and chemotherapy are adjuncts to management.

Wounds of the Chest.—In approximately 10 per cent of the wounded admitted to a hospital the major injury is of the chest.

* Clarendon Ann Surg 193 J B Lippincott Co. Publisher

As with head injuries there is a high immediate battlefield mortality

In the management of thoracic wounds two distinct phases may be encountered—physiologic disturbance of the function of the cardiorespiratory system and infection. Physiologic disturbance must be corrected immediately in the most forward surgical installation. The hazards of infection are less urgent and may be controlled in an echelon further to the rear.

One of the most urgent complications is open *pneumothorax*—the so-called *sucking wound*. This must be closed immediately by a compress of gauze held in place by adhesive plaster. Closure by suture is not advisable, as tight closure is likely to be followed by pressure pneumothorax and surgical emphysema. After the patient reaches a surgical hospital the wound is debrided, hemostasis is effected and the deeper structures of the chest wall are approximated by suture so as to close the pleural cavity.

Pressure pneumothorax is controlled by insertion of a catheter with a flutter or water seal valve. Needle aspiration of air and blood from the pleural space, aspiration of blood and mucus from the tracheobronchial tree by catheter or bronchoscope, novocain injection of intercostal nerves, oxygen therapy and transfusion are important measures in the early management of thoracic injuries.

Indications for early thoracotomy either by extension of the wound or by separate incision at the site of election include continuing intrapleural hemorrhage not controlled by hemostasis in the chest wall, debridement, anatomic or clinical evidence that the missile may have penetrated the diaphragm, traverse through or lodgment of a missile in the mediastinum with possible visceral damage, large intrapleural foreign bodies or debris that is readily accessible by extension of the wound and wounds of the large bronchi.

Late complications are controlled as indications for intervention develop. Large intrapulmonary foreign bodies, particularly the irregular shaped high explosive fragments, are removed surgically. Residual hemothorax is managed by repeated aspiration. Large collection of clotted blood that can no longer be aspirated by needle and

show little evidence of absorption are evacuated by thoracotomy with decortication of the lung.

Post traumatic empyema may require surgical drainage or preferably a more radical thoracotomy. Complete removal of residual clotted blood with decortication of the lung even in the presence of infection promotes rapid healing and full restoration of pulmonary function. Penicillin is utilized both systemically and locally in the pleural space. Every effort is made to prevent or cut short the complications of thoracic wound that lead to chronic disability.

Wounds of the Abdomen—In 3 to 5 per cent of the wounded in action who survive to be admitted to a hospital the wound is classified as abdominal. Of these 80 per cent or less have penetration of the peritoneal cavity with injury to one or more hollow or solid viscera. Concomitant injuries from the same or other missiles are present in three fourths of the cases and contribute materially to the mortality rate. One fourth of the cases are complicated by compound fractures or traumatic amputations.

The mortality rate for the group with visceral penetration is 30 per cent if deaths from late complications are included. Of those who die 42 per cent succumb to immediate sequelae of the wounds—hemorrhage and shock—or to irreparable destruction of vital organs. In 27 per cent death is due to pulmonary complications, peritonitis and associated injuries.

The critical decision is when to operate. If the state of shock does not respond rapidly to infusion of blood and plasma it is a fair assumption that there is continuing hemorrhage or established peritonitis and operation must be undertaken despite the poor condition of the patient. Transfusions are continued during and after the operation.

Small Bowel Perforation—Perforation of the small intestine is found alone in 20 per cent of cases and associated with other visceral wounds in an additional 20 per cent. Repair is made by suture or resection and anastomosis as the damage indicates. Exteriorization of the small bowel or double-barrelled enterostomy may appear to solve an immediate problem but leads to grave

complications and is to be avoided at all cost

Large Bowel Perforation—Perforation of the large intestine is found as the only injury in 10 per cent of cases and associated with other visceral injury in an additional 26 per cent. The distribution of injuries from cecum to rectum appears to be random. Patients with injury in the colon comprise the group with the highest mortality rate—approximately 50 per cent. When the colon alone is injured the death rate is not greatly different from that in cases of small bowel perforation.

In the surgical management of wounds of the large bowel the perforated segment is mobilized to permit exteriorization through a laterally placed separate abdominal incision. In the rectosigmoid area where mobilization is impossible the perforation is inverted by suture and proximal colostomy is performed. When circumstances permit exteriorization of a segment of large bowel is made with a view to later closure by crushing with a spur clamp.

Wounds of the rectum are characterized by inaccessibility, difficulty of diagnosis, a frequency of damage to other structures and the hazard of ascending retroperitoneal cellulitis. Every wound of the rectum demands a laparotomy, and with any perforation of the rectum above the splenicocolostomy is mandatory. The perforation of the rectum need not be sutured but wide posterior drainage is established.

Spleen—Injury to the spleen is found in 7 per cent of cases and as the only injury in 2.3 per cent. When the spleen alone is involved the mortality rate is 19 per cent. Splenectomy is the operation of choice.

Liver—Wounds of the liver are found in 30 per cent of cases. The mortality rate when the liver is the only viscus involved is 15 per cent. Hemorrhage may have ceased from small wounds of the liver if so they are not disturbed. High velocity penetrations may produce a shattering fracture of the liver that requires packing with gauze to control hemorrhage and drainage at dependent sites to provide for evacuation of escaping bile.

Kidney—Conservatism is the rule in dealing with the 10 per cent of penetrating abdominal wounds that involve the kidneys.

Nephrectomy is done for fragmentation of the organ and continuing hemorrhage.

Urinary Bladder—Perforation of the bladder occurs in 4.7 per cent of cases and is usually associated with wounds of other viscera. Repair is accompanied by suprapubic cystostomy in all cases.

Retroperitoneal Hemorrhage—Hemorrhage into the mesentery or in the retroperitoneal space presents signs and symptoms that may be indistinguishable from those of perforation of a viscus. Unless there is continuing hemorrhage no intervention is indicated after perforation of the bowel is excluded at laparotomy.

Trench Foot and Immersion Foot—Injury to the feet by cold and moisture for years has been an important cause of ineffectiveness in armies during winter campaigns. The condition was common during the static trench warfare in the winter months of World War I and became known as trench foot. The same term has been applied to the lesion in World War II. Trench foot is caused primarily by exposure of the feet to wet cold. Freezing temperatures are not necessary. The injury can be expected when the night temperature drops in 35° F. or below. The necessary duration of exposure varies inversely with the degree of cold. The injury may become manifest after five or six days of exposure or it may appear overnight.

Several factors contribute to the effectiveness of cold in producing the injury. Wet shoes and socks promote loss of heat from the feet by conduction and by evaporation. Mechanical impediments to the circulation of blood in the lower extremity aggravate the effects of reflex vasoconstriction in response to cold and destroy the body's most effective means of keeping the feet warm. The wearing of tight shoes and leggings, prolonged dependency, inactivity and resting in cramped positions are all predisposing factors. Cold and ischemia exert their effects upon the small blood vessels and nerves and possibly upon the peripheral layers of the epithelium.

Immersion foot is similar to trench foot and is indistinguishable from it clinically. It is seen among survivors exposed to wet cold in lifeboats or on life rafts. The causes, both primary and contributing are identical with

those of trench foot. The condition should be distinguished from the nutritional edema and neuritides that occur among survivors from sinkings in tropical waters although some element of nutritional insufficiency may be combined with the effects of cold in ordinary cases.

Three clinical stages of the reaction to injury are recognized. During the first or pre-inflammatory stage the soldier complains of cold numbness and mild pain in the foot and ankle. Slight swelling is the rule when there has been intermittent warming. The second or inflammatory stage begins when the shoes are removed and the foot dries and becomes warm. The pain then becomes tingling in character and more intense. The appearance of the skin changes from a wrinkled surface of white or blue color to that of a smooth red bluish. Swelling begins and progresses rapidly so that the shoe cannot be replaced. Blisters may appear during the next twenty-four hours. They generally contain clear fluid but at times the fluid is bloody. Tender areas of ecchymosis appear in the skin of the dorsum or other parts of the foot and these may progress to frank gangrene. The gangrene extends for varying depths and may involve only the superficial layers of the skin or the entire thickness of the foot. The inflammatory stage generally lasts two to four weeks by which time the edema has subsided and the redness has disappeared. The skin is now pale and waxy white. Rarely it is pigmented. It is of delicate texture has begun to sweat and is moderately or abnormally cold to touch. This is the postinflammatory stage. In some cases hyperhidrosis and abnormal sensitivity of the feet to temperature changes develop. Pain is no longer tingling in character but is deep seated and is similar to the pain of rheumatoid arthritis particularly about the first metatarsophalangeal joint. It is usually worse at night and it changes with the weather.

The postinflammatory stage varies in duration and offers the greatest problem in treatment. Many soldiers can be returned to duty within six weeks and the majority within twelve weeks. In about 90 per cent of the cases however so much fibrosis and atrophy will have been incurred in the ligaments and muscles of the foot that even

after six months of treatment the men are unable to perform any but the lightest duties. In some cases the hyperhidrosis and oversensitivity to cold appear to be permanent.

Prevention—Education is of first importance for the prevention of trench foot. The soldier must be repeatedly instructed in principles of foot hygiene. He must be taught methods of keeping the feet warm and dry under adverse conditions. A daily change to dry woolen socks is recommended. Extra socks are carried or supplied daily. Above all he is instructed not to go to sleep at night with wet socks and foot gear. Every effort is made to stimulate the circulation in the feet. This is accomplished by foot exercises by avoiding dependency and by massage at the time the feet are dried and socks changed. The shoes and leggings must fit loosely at all times. Cramped positions and immobility are avoided. The clothing must be designed to prevent heat loss from the body in general yet to minimize the collection of perspiration during activity.

Treatment—During the first and second stages absolute bed rest is maintained to avoid further trauma to already injured tissues. Heat in any form is strictly avoided. The feet are kept slightly elevated if the position is tolerated and exposed to a cool atmosphere. The optimum temperature of the skin is between 65° and 70° F. and may be relieved with the help of an electric fan and if necessary with a spray of water from the fan blades. Some have advocated extreme cooling with slow elevation to room temperature. The evidence is as yet insufficient however to warrant acceptance of the procedure.

The pain associated with the disease has not been relieved consistently by block of the lumbar sympathetic chain or by actual lumbar ganglionectomy. Sympathectomy is recommended when there is objective evidence of deficient circulation with actual or impending gangrene. Amputation of gangrenous parts is delayed as long as possible. The inflammatory reaction of the second stage of the disease must not be confused with the cellulitis of infection.

Rehabilitation is an important part of therapy. Foot and vascular exercises are taught the patient. Physiotherapy and foot

VII. TENDONS, TENDON SHEATHS AND FASCIAL SPACES

INFECTIONS OF THE TENDON SHEATHS OF THE HAND AND OF THE FASCIAL SPACES OF THE PALM

TENDON SHEATH INFECTIONS

Tendon sheath infections usually result from direct inoculation of a tendon sheath by a penetrating object or from extension of infection in the subcutaneous tissues.* Direct inoculation can occur during incision for drainage of a felon but extension to the

Fig. 44—Diagram showing the position and extent of the flexor tendon sheaths and of the fascial spaces of the palm (After Haszard)

tendon sheath almost never occurs as a result of paronychia or of infections of the dorsal surface of a digit. Since infection spreads rapidly throughout the extent of the closed tendon sheath and secondarily

* The author has seen only two cases of metastatic pyogenic infection of a flexor tendon sheath: one of the flexor tendon sheath of the index finger in a woman with acute rheumatic fever and multiple involvement of the joints; the other of the ulnar bursa and common flexor sheath above the wrist in a four-year-old girl convalescing from an attack of measles

through any sheaths that communicate with the one first involved destruction of the tendon and its synovial sheath ensues in a very short time unless the infected space is adequately drained and secondary infection avoided.

The flexor tendon sheaths of the index, middle and ring fingers extend from a point just distal to the distal flexion crease of the fingers to a line closely approximating the distal flexion crease of the palm (Fig. 44). They lie in close apposition to the palmar surface of the phalanges and are separated from the bone only by a thin layer of connective tissue. An infection of the flexor sheath of any of these fingers makes itself evident very promptly by pain, swelling, inability to extend the finger completely (Figs. 45-47) and by tenderness which corresponds definitely and accurately to the anatomical outline of the tendon sheath.

The sheath of the long flexor of the thumb begins at a point slightly distal to the distal flexion crease of the thumb, surrounds the flexor pollicis longus in the palm and terminates a thumb's breadth above the anterior annular ligament (Fig. 44). Over the first metacarpal bone it lies between the flexor pollicis brevis and the adductor obliquus. The motor branch of the median nerve to the muscles of the thenar eminence as it arises from one of the digital branches to the thumb at a variable distance (from 1 to 2 inches) below the wrist lies superficial to the tendon sheath. The radial bursa is the proximal portion of the sheath of the flexor pollicis longus; it is denoted, ends in a blind pouch whose posterior portion rests on the pronator quadratus and is separated by the latter from the wrist joint and the radio-ulnar joint.

The sheath of the flexor tendons of the little finger begins just distal to the distal flexion crease of the fifth finger and extends proximally to become continuous in the majority of cases with the ulnar bursa, a good sized sac whose posterior wall in the palm lies over the metacarpal bone of the

ring finger and the base of the middle metacarpal bone. Like the radial bursa the ulnar bursa extends proximalward under the an-

pushed radialward, as it were, in three pockets—one superficial to the tendons, one between the superficial and deep tendons

Fig. 43—Infection of the flexor tendon sheath of the index finger resulting in diffuse swelling of the entire finger, more marked on the dorsal aspect. The finger is held in the characteristic position of semiflexion. A small and ineffectual incision, which does not extend to the affected sheath, has been made on the radial side of the finger.

terior annular ligament approximately a thumb's breadth above the ligament (Fig. 44). Its posterior wall lies underneath the flexor tendons, on the pronator quadratus

and one, the largest and most easily distensible, underneath the deep tendons. The exact arrangement of the flexor tendon sheaths in the proximal portion of the palm

Fig. 46—Infection of the middle palmar space secondary to an infection of the flexor tendon sheath of the middle finger.

muscle, and separated by the muscle from the wrist joint. In the region of the wrist joint the ulnar bursa forms a more or less complete sheath for the flexor tendons, being

and over the wrist is subject to some variation, but the important fact, from a practical standpoint, is that in the majority of cases the radial and ulnar bursae communi-

cate with one another. As a result an infection arising in the tendon sheath of the fifth finger involves the same structures in the

Fig. 47—Infection of the middle palmar space secondary to a neglected infection of the flexor tendon sheath of the ring finger. In this case pus is passing to the dorsum of the hand in the subcutaneous tissue distal to the web between the ring and little fingers.

Fig. 48—Neglected infection of the tendon sheath of the flexor pollicis longus which has spread into the forearm and into the ulnar bursa above the wrist. Because it was difficult to be certain if the infection had passed distalward into the palm along the flexor tendon sheath of the fifth finger the first incision was made over the ulnar bursa in the palm (c). The shining tendon could be seen through its synovial covering so the sheath was not opened (a and b). Before operation, c, d and e appearance of the hand and forearm immediately after incising the palm over the ulnar bursa draining the retroflexor space above the wrist through an incision on the ulnar side of the forearm (d) and draining the sheath of the flexor pollicis longus and the radial bursa in the palm.

and radial bursa usually extends to the ulnar bursa and distally along the tendon sheath of the little finger (Fig. 50), and an infec-

tion arising in the tendon sheath of the fifth finger involves the same structures in the reverse order. From these various sites infection may extend to a number of different places, as will be indicated later.

Diagnosis.—The diagnosis of a tendon sheath infection is based on symptoms which, early in the course of the infection are limited to the area involved but which tend very quickly to become more difficult of interpretation because of extension of the infection to surrounding tissues. The symptoms are pain, tenderness, and other signs of inflammation frequently out of proportion to the extent of the infected area. The patient holds the affected finger in a slightly flexed position (Figs 45-47). Any attempt to extend it causes him to wince with pain. By gentle pressure an area of tenderness can be outlined which corresponds accurately to the anatomical out-

line of the tendon sheath. In every case the dorsum of the affected finger is swollen and edematous (Figs 45-47) because of the direction of lymphatic drainage and the greater distensibility of the tissues of the dorsum of the hand as compared with those of the palmar surface. Of these symptoms the diffuse symmetrical swelling of the entire finger and the wincing pain which results from even a slight effort toward extending the finger are particularly significant. Not infrequently one sees infection of the subcutaneous tissues of the palmar surface of a finger, which causes acute pain and tenderness with considerable swelling and which immediately suggests the possibility of infection within the tendon sheath. In such cases the asymmetrical character of the swelling and still more

Fig. 49.—Infection of the sheath of the flexor pollicis longus, radial bursa of the wrist, and of the sheath of the little finger secondary to a trivial injury of the thumb. (See also Fig. 36.)

however, and careful examination of the wound should make the diagnosis clear.

If the infection involves only the index, middle or ring finger there should be no doubt as to its location and the freedom of other fingers from infection. With infection of the radial and ulnar bursae the inflamed swollen wrist (Figs 48 and 49), with the tense anterior annular ligament drawn like a taut cord across its volar surface suggests at once the extension of the infection into the forearm. Since in more than 80 per cent of cases the radial bursa communicates with the ulnar bursa above the wrist it is common to find involvement of both. In early cases, however, it may be difficult to determine whether one is dealing with one of the less common types in which the bursae do not communicate with

the freedom from pain on gentle flexion and extension of the finger show that the infection has not yet penetrated the sheath. If such a finger is incised promptly and adequately with care not to carry the incision and the infection into the perhaps exposed but still undamaged sheath the patient recovers rapidly and the more serious condition a suppurative tenosynovitis is avoided. If as occasionally happens as a result of a deep knife cut a tendon sheath is opened and infection of the tendon sheath follows the wincing pain on attempted extension of the finger is lacking because the exudate is no longer held under tension in a closed space. The other characteristic symptoms

however, and careful examination of the wound should make the diagnosis clear.

one another. If for example the infection has begun in the thumb and spread into the radial bursa one may be uncertain whether the ulnar bursa and the tendon sheath of the fifth finger are involved. In such a case the position in which the fifth finger is held, the presence of pain on attempted extension of the finger and the

Fig. 60.—Same case as shown in the previous figure. Diagram showing the site of injury and the extension of the infection. The stippled area indicates the extent of the intense inflammatory reaction on the solid black area, the site of abscess formation.

presence of a point of maximum tenderness where the distal flexion crease of the palm crosses the flexor tendons of the fifth finger (Kanavel's sign) are important considerations. If one is still in doubt it is wise through a bloodless field to make an exploratory incision over the ulnar bursa in the palm (Fig. 48). If no infection is present within the bursa the subcutaneous tissues have a normal appearance and more

deeply one can see through the synovial sheath the shining tendon moving back and forth with movement of the finger. If infection is present within the bursa the subcutaneous tissues are edematous and swollen. When the bursa itself is exposed a characteristic change is immediately apparent. The synovial sheath is no longer translucent but grayish white and opaque. The distended bursa usually bulges into the field and the moment it is nicked with the knife blade pus escapes into the field. If no infection is present within the bursa and the incision over it is made first of all before instruments and operative field are contaminated no harm will be done by such a procedure but irreparable injury may be done to the tendon if an infected sheath is not drained. If the primary infection involves the tendon sheath of the fifth finger, the same considerations apply in a reversed order with reference to the radial bursa and the flexor tendon sheath of the thumb.

In cases which have been neglected for four or five days or which have been drained inadequately the median and ulnar nerves may be so compressed by the pressure of the exudate above the wrist as to be partially anesthetized. In such cases the characteristic symptoms mentioned above—particularly the excruciating pain caused by attempted extension of the affected finger—are masked but the history, the location of the primary lesion, the bulging swelling above the wrist and the general symptoms of severe infection make the diagnosis clear.

When rupture of the tendon sheaths of the index, middle or ring fingers takes place the pus spreads into one of the fascial spaces of the palm and forms an abscess of the thenar space or the middle palmar space (Figs. 44 and 50). (These will be discussed under infections of the fascial spaces.) When rupture takes place from the radial or ulnar bursa the pus at first lies in the retroflexor space between the flexor tendons and the pronator quadratus (Fig. 51). As it spreads upward it dissects between the superficial and deep flexor muscles and tends to become superficial along the ulnar side of the upper third of the forearm. In such an event the entire hand and forearm are dusky red, swollen, tense and edematous. Vesicles or blebs may cover large areas of the affected

extremity. Because of the extent of the involvement and the retention of a large amount of pus under pressure toxic absorption proceeds at a rapid rate and the general symptoms of severe infection—high

distalward from the thenar and middle palmar spaces along the lumbrical muscles. Infection of the fascial spaces of the palm may occur by direct inoculation as the result of a penetrating wound but most com-

Fig. 51.—The retroflexor space above the wrist into which pus ruptures from a distended radial or ulnar bursa. (After Kanavel)

fever, rapid pulse, profuse perspiration, prostration and not uncommonly delirium—indicate the extreme gravity of the condition.

monly occurs as the result of extension from a tendon sheath.

The thenar space (Figs. 44 and 52) lies upon the adductor muscles of the thumb

Fig. 52.—Cross section of the palm just proximal to the metacarpal bases, showing the position of the thenar and middle palmar spaces. (After Kanavel)

INFECTION OF THE FASCIAL SPACES OF THE PALM

The important fascial spaces of the palm are the thenar space, the middle palmar space and the lumbrical canals which extend

partially covered by the short muscles of the thenar eminence, by the flexor tendons of the index finger and by the neurovascular digital vessels and nerves. It extends ulnaward as far as the middle metacarpal

bone The middle palmar space (Figs 44 and 52) lies deep in the palm underneath the flexor tendons of the middle and ring fingers Its floor is formed by the volar interosseous muscles and metacarpal bones On the radial side it extends to the middle metacarpal bone On the ulnar side it is partially covered by the distal end of the ulnar bursa

Tendon sheath infections arising in the index finger tend to rupture into the thenar space Tendon sheath infections arising in the middle and ring fingers usually rupture into the middle palmar space In neglected cases tendon sheath infection starting in the thumb may rupture into the thenar space and tendon sheath infections arising in the fifth finger into the middle palmar space but such an event is very uncommon

With infection of the middle palmar space the striking symptoms are the loss of the normal convexity of the palm and the edema and swelling of the dorsum of the hand (Figs 46 and 47) Because the pus lies under the firm palmar fascia and under the flexor tendons the palmar swelling is not pronounced but it is sufficient to change the normal convexity of the palm into a slight convexity Because of the direction of lymphatic drainage the dorsum of the hand is swollen and edematous but pus is not present on the dorsum except in neglected cases in which the infection has extended distalward along the lumbrical canals and passed to the dorsum of the hand in the subcutaneous tissue about the web of the fingers (Fig 47) Only in grave neglected infections in which osteomyelitis has taken

Fig 53—Infection of the thenar space Note the swelling over the dorsum between the thumb and index finger the forced abduction of the thumb from the palm c Incision for draining the thenar space d desired the incision can be made in a direct parallel to the volar margin instead of vertically

With pus under great tension rupture from one space into the other may take place

The symptoms of thenar space infection are pain tenderness and swelling of the thenar area both on its palmar and dorsal aspects Normally the thenar eminence is the most prominent portion of the palm but with infection in the thenar space it stands out in such a pronounced fashion as to elevate the thenar eminence still more above the remainder of the palm and force the thumb away from the hand (Fig 53) The dorsum of the web between the thumb and index finger is swollen and edematous Eventually there is extension of the infection along the lumbrical canal on the radial side of the index finger with tenderness and swelling on the dorsum of the hand between the index and middle fingers

place does pus find its way directly through the barrier of deep fascia interosseous muscles and metacarpal bones from palm to dorsal surface

THE EXTENSOR TENDON SHEATHS

The extensor tendons are enclosed in synovial sheaths only where they pass underneath the dorsal carpal ligament The six compartments underneath the ligaments are lined with a synovial membrane whose vascular layer furnishes a covering for the tendons These sheaths particularly those of the extensors of the thumb are not infrequently the site of a low grade infection which makes itself evident by local pain and tenderness exaggerated by movement of the affected tendons and by a soft palpable crepitation as the tendon moves back

and forth in its sheath. They are not commonly the site of a suppurative inflammatory process.*

TREATMENT OF TENDON SHEATH AND FASCIAL SPACE INFECTIONS

The treatment of infections of the tendon sheaths and fascial spaces is to secure adequate drainage as soon as the condition is recognized. This should be done under a general anesthetic such as nitrous oxide, ethylene or ether, and through a bloodless field secured with the aid of a constrictor.

In draining the tendon sheaths of the fingers the incision should be made well to the side of the finger (Fig. 51), to avoid

dorsalward and not lifted palmarward as the tendon sheath is sought for.

To expose the tendon sheath it is necessary to retract well the edematous and swollen subcutaneous tissue which overlies the tough and inexpandible fibrous tendon sheath. If one can then expose the synovial sheath for a little distance before incising it one will find, instead of a thin translucent membrane through which the shining tendon may be discerned, a grayish edematous structure which resembles the edematous peritoneum overlying an appendiceal abscess. The moment it is opened the pus pours out. In very rare cases the pus may be confined to the space underneath the

Fig. 51—*a*, Incisions for draining the digital sheaths, *b*, the sheath of the flexor pollicis longus, *c*, the ulnar bursa in the palm, *d*, the retroflexor space above the wrist, *e*, the middle palmar space, *f*, the thenar space.

the flexion creases on the palmar surface and to prevent herniation of the tendon from its sheath, a complication that occurs very promptly if the sheath is opened through a midline incision. The digital nerves and blood vessels should be sought for immediately after the skin incision is made and drawn to one side. Since the digital vessels lie lateral to the nerve and slightly dorsal to it, they are safe from injury if both nerve and vessels are retracted

tendon and appear only when the tendon is gently lifted from the sheath.

If the flexor sheaths of the thumb and little finger are involved the four incisions indicated in figure 51 should be made. One should avoid cutting through the muscles of the thenar eminence in the case of the thumb by making a curved incision to the ulnar side of the thenar eminence (Fig. 48, *c*) and retracting the thenar muscles radialward. The digital nerves to the thumb should be visualized and injury to the nerves carefully avoided. Division of the motor branch to the thenar muscles results in thenar atrophy and loss of the ability to rotate the thumb so that it faces the fingers.

* The writer has seen only two cases in ten years. One followed a penetrating wound from a fish hook; the second a dog bite. In the second case because drainage was not instituted promptly, the infection spread over the entire metacarpus underneath the extensor tendons and dorsal aponeurosis.

In incising the ulnar bursa in the palm (Fig 48 c) one should remember that the flexor tendons of the little finger run obliquely upward and radialward and not in the line of the fifth metacarpal bone and that the digital branches of the ulnar nerve to adjacent sides of little and ring fingers lie superficial to the flexor tendons and their synovial sheaths. The incision in the forearm to drain the upper most distensible portions of the ulnar and radial bursae and the retroflexor space should always be made at the side of the forearm (Fig 48 d), never over the middle of the volar surface for the pus lies underneath the flexor tendons (Fig 51). Incision over the volar surface of the forearm to drain the retroflexor space inevitably leads to extensive fibrosis and destruction of tendons and frequently to injury of the median nerve. An incision on the ulnar side alone is adequate for drainage of both bursae; it should be made as close as possible to the volar surface of the ulna so as to avoid injury of the overlying ulnar vessels and nerve.

The middle palmar space is drained through an incision along the distal flexion crease of the palm (Fig 54). This incision as Bunnell and others have pointed out avoids the risk of leaving a palmar scar transverse to the lines of skin cleavage as a possible cause of a flexion contracture. The flexor tendons, digital nerves and blood vessels of the middle finger are retracted to the radial side and the corresponding structures of the ring finger to the ulnar side. The middle palmar space as it lies behind the flexor tendons is then widely exposed. Through the incision indicated for drainage of the thenar space (Fig 53) a pair of forceps or Kocher dissector can be passed upward and ulnarward directly into the abscess cavity as it lies on the adductor muscles of the thumb.

If drainage incisions are located correctly and of adequate length an incision on one side of the affected fingers and on the ulnar side of the forearm in the case of ulnar and radial bursae infections suffices for drainage. The use of through and through drainage above or underneath a flexor tendon should be carefully avoided. It is the surest possible method of causing necrosis of the tendons.

With infections of the middle palmar and thenar spaces drains should never be inserted through and through from the palm to the dorsum of the hand. The spaces in question are separated from the dorsal surface by a number of anatomical layers (Fig 52). Plunging a pair of forceps through the deep volar fascia, the interosseous muscles between metacarpal bones and through the dorsal aponeurotic and subcutaneous layers in order to drain an accumulation of pus in one of the fascial spaces of the palm renders almost certain the development of osteomyelitis and the formation of persistent sinuses.

AFTER TREATMENT OF TENDON SHEATH AND FASCIAL SPACE INFECTIONS

In order to stop venous oozing after operations and to keep wound edges widely separated drainage wounds are packed lightly with gauze impregnated with petrolatum. Occasionally rubber tissue is used instead. Drainage tubes are never used be-

Fig 55—The position of flexion (Kanavel)

cause pressure necrosis of tendons and tendon sheaths and extensive fibrosis involving tendons and nerves inevitably result from their use.

After bleeding has been arrested a large sterile towel is laid on the arm board covered with abdominal pads and sterile dress-

ings, and the outstretched arm is laid on the bed of dressings. More dressings are added to cover the arm; the dressings are saturated with warm, sterile boric or salt solution and the edges of the towel brought together over the whole. The warm solution is added at two-hour intervals without changing the dressing, and a powerful electric light or an electric heater is placed above the arm to help maintain the warmth.

At the end of twenty-four hours the dressings and drains are removed and a sterile dressing is reapplied with the same care that was used in applying the original dressing. If one can avoid adding secondary infection, particularly in streptococcal infections of the tendon sheaths the tendons may be saved and a complete restoration of

in the bath the patient is urged to move his fingers gently to prevent the formation of fibrous adhesions. Simply moving the fingers once or twice daily through as complete a range of motion as can be accomplished without pain suffices to prevent the formation of crippling adhesions. As soon as the intermittent soaking and smaller dressing can be substituted for the continuous wet dressing a light aluminum splint is applied outside the dressings to maintain the hand and the fingers in the position of function (Fig. 55). When the danger of lighting up the infection has passed, physical therapy and active exercises are begun so that restoration of function may keep pace with the healing of the tissues. If this ideal is kept in mind the disability that so fre-

Fig. 55—Same case as shown in figure 49 showing the degree of function present nine months after operation

function secured in a considerable proportion of cases.

No drainage material is reinserted after removal of the original drains. Repeated introduction of a drain almost certainly adds further infection to the open wound.

As soon as the acute symptoms have subsided, usually at the end of three or four days, an arm bath, used for fifteen or twenty minutes twice daily, is substituted for the continuous moist dressing. After being soaked in a warm, sterile solution the arm is laid on a sterile towel, allowed to dry for a half hour under an electric light and then covered with a dry dressing or with a thin moist dressing covered by dry dressings. Care is used to make the dressing large enough to prevent wound secretion from saturating it, but not so large as to cover the tips of the fingers and render their movement impossible. While the hand is

quickly continues long after the infection is overcome and the drainage wounds have healed can be reduced to a minimum (Fig. 56).

TUBERCULOUS TENOSYNOVITIS

Tuberculous tenosynovitis is a specific chronic infection of the bursae and tendon sheaths of the hand and foot.

Etiology.—It is slightly more frequent among females than males, is most often seen in young adults and adults and involves the right hand more than twice as frequently as the left. The disease is usually primary and it is unusual to discover active tuberculosis elsewhere. Except for the actual inoculation of tendon sheaths it is difficult to prove or disprove a traumatic origin and although many patients associate the disease with injury the tendency today is to question seriously any causal relationship. Adams, Jones and Marble have called attention to the reduced incidence of the disease in butchers since the decline of bovine tuberculosis and the enforcement of stricter pure food laws.

Pathology.—*Localization.*—The radial and ulnar bursae of the hand are the most frequently involved; next in frequency are the dorsal tendon sheaths of the hand, then the digital sheaths of the index, middle and ring fingers and last the tendon sheaths on the dorsum of the foot. The radial and ulnar bursae are always infected together but their distal prolongations into the thumb (frequently) and little finger (rarely) may remain free from disease. The process is so rarely bilateral that the presence of such involvement practically excludes tuberculosis.

Gross Pathology.—The sheaths may be but slightly thickened and injected and contain a moderate amount of yellow serous

fluid. More often however both parietal and visceral layers are thick and shaggy (Fig 57) and the enclosed tendons are gray and lusterless while in the small amount of yellow fluid are fibrin flakes and rice bodies. There may be extensive formation of granulation tissue with caseation and destruction with or without rice body formation. As the disease progresses the tendons are invaded and in fully 75 per cent of cases serious tendon destruction will be found and in some 50 per cent whole segments of tendon will be destroyed or so badly fragmented as to require removal. In neglected cases the associated structures—bones, joints and muscles—are invaded and cold abscesses form with their attendant danger of secondary infection. The median nerve though compressed and swollen is never infiltrated.

The rice bodies or melon seed bodies found in about 50 per cent of cases are small shiny grayish ovoid or kidney shaped flattened or faceted masses varying in length from 1 to 15 mm., and in number from one or two to many hundreds. They are probably the result of the mechanical action of the moving tendons on fibrin encrusted products of necrosis of the tendon sheath.

Symptoms and Course.—The disease is characterized by the insidious development of a slowly progressive painful or painless swelling over the anatomic area of the involved sheaths (Fig 58). In one third of the cases the swelling is preceded by sensory or functional disturbance such as painful tingling numbness or prickling sensations or by stiffness in one or more fingers. These premonitory symptoms may persist for many weeks or months before the actual swelling appears. A leathery crepitus as in traumatic tenosynovitis may occasionally usher in the tuberculous process.

The swelling often appears as a sudden diffuse edema which responds to heat and rest only to be replaced later by the more tense localized swelling. With involvement of the radial and ulnar bursae the swelling begins at the wrist and extends slowly into the palm whence it may proceed down over the volar surfaces of the thumb and little finger. With involvement of the digital sheaths of the index, middle and ring fin-

gers the swelling first appears over the proximal phalanx and then extends upward into the cul-de-sac of the sheath in the palm. In cases of long standing the disease spreads beyond the limits of the sheath and leads to swellings in the middle palmar space, thenar space or fascial spaces of the forearm.

to seek relief by the application of heat or cold. After persisting for several months or a year the pain usually subsides even though the swelling slowly increases.

In the early stages of the disease the patient has good use of the part except for the associated pain. Stiffness, weakness and difficulty in closing the fist soon develop

useless and the formation of cold abscesses and secondary infection may necessitate amputation and threaten the patient's life.

Examination—Tuberculous tenosynovitis produces a fusiform swelling (Fig 58) which in the early stages may not be apparent unless compared with the sound side. The swelling at the wrist is incompletely divided into a proximal and distal half by the transverse carpal or dorsal carpal ligament (Fig 58 *b* to *e*). On the dorsum of the wrist the several longitudinal compartments can be made out corresponding to the dorsal tendon sheaths. Disease of the digital sheaths produces a swelling resembling spinar ventosa. If rice bodies are present they give a sensation resembling lead shot in a leather bag and produce a peculiar

scopic pathologic picture so closely resembling that of tuberculosis that the differentiation is very difficult. There may occur an acute or subacute inflammation in the early secondary stage and the luetic hygroma and chronic gummatous type in the tertiary stage. The condition is likely to be bilateral, is rarely painful and causes few or no functional symptoms. The diagnosis is established by the presence of associated lesions, a positive serum reaction and response to specific therapy.

Gonorrheal tenosynovitis occurs most often in males, is metastatic secondary to a urethral infection or more rarely to a vaginitis or ophthalmitis and may follow instrumentation. The onset is acute (rarely insidious) with rapidly developing pain and

grating crepitus when the patient is asked to move his fingers. A moderate amount of atrophy of the associated muscles occurs. There is little or no increase in the temperature of the part and the skin is normal unless cold abscesses, sinuses or infection are present.

Diagnosis—Tuberculous tenosynovitis must be differentiated from other forms of chronic tenosynovitis and from tumors of the tendon sheaths.

Chronic non-specific tenosynovitis produces a clinical and gross pathologic picture so closely resembling that of tuberculosis that microscopic section is required to make the diagnosis. Bilateral chronic tenosynovitis is almost always non-specific.

Syphilitic tenosynovitis is very rare and may produce a clinical gross and micro-

scopic picture so closely resembling that of tuberculosis that the differentiation is very difficult. There is produced a very tender swelling over the course of the tendon sheath with little or no change in the overlying skin. Aspiration of the swelling yields a cloudy, serofibrinous or even purulent fluid. In the early stages rest, heat, plenty of fluids and immobilization of the part in proper splints often lead to rapid subsidence of symptoms. Aspiration of the fluid is helpful but instrumentation and mechanical tampering with the original focus are inadvisable. The immobilization should be maintained no longer than necessary, and it is important to start physical therapy as early as possible.

The common dorsal ganglion produces a tense, circumscribed globoid swelling on the dorsum of the wrist, most often on the

*Mason: Surg., Gynec. & Obst. 59.

radial side and rarely reaches greater than hazelnut size

Xanthomatous tumor of the tendon sheaths may occasionally lead to confusion when it occurs as a diffuse tumor at the wrist instead of a circumscribed smooth nodular swelling of a finger. It is however firmer and more nodular than tenosynovitis and fluctuation is absent.

Arborescent lipoma is a rare condition in which a fatty branching tumor spreads throughout the sheath. It grows slowly and insidiously and causes few or no functional symptoms. According to Strauss these tumors harden when they have been exposed to cold.

Prognosis.—The prognosis for tuberculous tenosynovitis is good; few patients will be found with active tuberculosis elsewhere and unless grossly neglected the local process should not threaten life. If treated early and properly a primary cure should be obtained in the majority of cases but in a few repeated operations will be necessary. The functional results are good though in an occasional case amputation of a digit or an extremity may be necessary.

Treatment.—The management should be directed both toward the local lesion and toward the general state of the patient as emphasized by Adams Jones and Marble. The treatment of choice for the local lesion is complete surgical excision of all diseased tissue. If the diagnosis is uncertain the surgeon may temporize for a short time with immobilization and heat but this should not be persisted in after the diagnosis is made. Complete surgical excision is an extensive and time-consuming procedure which if carried out thoroughly justifies all of the pains taken. The operation is performed under a gas (occasionally local) anesthetic in a bloodless field secured by means of a blood-pressure apparatus. Appropriate incisions are made avoiding as much as possible midline incisions and incisions crossing flexion creases and great care is taken to identify and isolate all important nerves and blood vessels. The tuberculous sheath is opened and each tendon taken in turn and carefully stripped of diseased tissue after which the parietal portions of the sheath are excised (Fig. 57). Fragmented and diseased portions of tendons must be removed and

it may be necessary to repair tendon defects by means of a suture or tendon graft.

Other less radical procedures are not to be recommended. Partial excisions, simple drainage, simple removal of rice bodies and the injection of iodiform or other emulsions offer by no means the favorable prognosis of thorough excision. Roentgenotherapy deserves serious consideration in those cases in which operation is not feasible or in which radical excision has failed to obtain a cure.

INJURIES OF TENDONS

LUXATION OF TENDONS

Dislocation of tendons from their normal channels may be caused by congenital malformation, deformity, trauma to the restraining ligaments, fracture or arthritis. The symptoms are pain, a feeling of weakness and disability due to the fact that the tendon is working at a mechanical disadvantage. The tendons that pull around a bony convexity and from slight abnormality, are prone to dislocate; are the extensor of the finger over the head of the metacarpal bone, the long head of the biceps in the bicipital groove, a fascial band which slips over the great trochanter of the femur, the patella, the peroneus longus and brevis, and the tibialis posterior. The tendons which dislocate

vertically from their channels because of defects in their restraining annular ligaments due to trauma or disease are the flexors of the digits the flexors and extensors in the wrist and the dorsal extensors of the foot. Because of an angular deformity at a joint a tendon may dislocate sideways spanning across a joint and so change its function that the motion produced is in a plane at even 90 degrees from the normal. Common examples are the dislocation of the extensor longus hallucis in bunion and of the peroneal tendons in talipes calcaneus. Flexor tendons in the forearm may dislocate over each other with a snapping sound because of their angle of pull and thickening of the paratenon.

Long Head of the Biceps—The long head of the biceps may slip forward from the bicipital groove in abduction and external rotation following trauma, congenital malformation or arthritis. There is a painful snap followed by pain, tenderness, weakness and disability in lifting in the forward and abducted positions. The treatment is to fix the tendon to the head of the humerus or to the coracoid process or to reconstruct the groove which has been filled with fibrous tissue by building up the inner bony lip and reconstructing the restraining ligament with fascia. (See section on Muscles and Ligaments.)

Flexor Tendon of the Finger—A median longitudinal volar incision in a finger is pernicious as it severs the annular bands or pulleys opposite the centers of the proximal and middle phalanges and the head of the metacarpal and so allows the flexor tendons to spin around the concavity of the flexed finger like bow strings with loss of their mechanical efficiency. A pulley may be reconstructed by encircling the tendon and bone with a free graft of fascia or tendon. Annular ligaments on the dorsum or flexor aspects of the wrist and on the dorsum of the foot can be reconstructed by fascial grafts.

Extensor Tendon of the Finger—When an extensor tendon slips off a knuckle it not only deviates the finger to that side but cannot extend the proximal finger joint. The tendon may be held in place by reconstructing the transverse ligamentous tissue with a small fascial graft and also if necessary by transposing the strip of main tendon of the

dorsal aponeurosis which caps the joint to a corrected position in this aponeurosis.

Snapping Hip—Occasionally there is a thickened tendinous band on the deep surface of the gluteus maximus which when the knee is flexed and the hip internally rotated can be felt to slip forward over the trochanter of the femur causing annoyance. The remedy is to divide the band and suture it backward from the trochanter.

Dislocating Patella—When the line of pull of the quadriceps tendon to the tibial tubercle lies external to its sesamoid bone (the patella) and the outer condyle of the femur does not stand sufficiently forward the patella dislocates outward when the knee is forcefully extended. Considerable disability results. The patient cannot indulge in sports because at any time the dislocation may occur and cause him to fall. Operation must be rather radical and a mere fascial graft is insufficient. The whole tibial tuberosity should be chiseled off and displaced inward at least 1 inch and there embedded under an osteoperiosteal flap and sutured with chromic catgut. The ligamentous capsule of the knee on the outer side is slit longitudinally for 3 inches and allowed to gap. On the inner side the capsule is narrowed by dissecting up a similar sized tongue of ligament with its base attached to the tibia. This tongue is then threaded diagonally across the patellar tendon and sutured to the outer corner of the patella and the gap left in the inner side of the capsule is closed by suture.

Peroneal Tendons—Starting usually between the ages of eight and twenty years and because of a congenitally shallow groove often bilateral the peroneal tendons either the longus or both dislocate and can be felt beneath the skin over the outer malleolus. The dislocation may first start with a sprain in inversion and dorsiflexion in which the annular ligament is torn or stretched but later it may become habitual and occur at inopportune times. When it first happens pain, tenderness, swelling and ecchymosis result. In recurrences the patient feels something give way and is lame and partially disabled. In talipes calcaneus it occurs without symptoms. In a recent case a felt pad is stripped on with adhesive plaster to return the tendons in place. The use of a walking cast is advisable until the an-

nular ligament is repaired. A brace may be used to prevent the motions from causing dislocation. In the operative repair the posterolateral border of the malleolus is built up with bone graft or the outer aspect of the malleolus may be so cut out that it can be slid backward in a groove on the malleolus. The annular ligament is then reconstructed by a fascial graft.

RUPTURE OF TENDONS AND MUSCLES

(See section on *Rupture of Muscles*)

Rupture of tendons and muscles partial or complete occurs as a result of direct trauma especially when under voluntary tension but more frequently indirectly from excessive tension from either voluntary contraction or passive strain. Commonly a direct blow on a contracted muscle belly ruptures the fascia and muscle fibers locally and a blow from an angular object on a tense tendon against a bone may rupture it at once or cause such reaction that delayed rupture occurs from some slight strain several weeks later. Sudden violent muscular contraction against resistance may result in rupture anywhere from the origin to the insertion including less commonly even the tendon itself. The usual sites of rupture in voluntary or passive strain are at the musculotendinous juncture at the origin or the insertion either with or without evulsion of some bone or across the muscle belly itself either partially or completely. In some instances the tears in the muscle are multiple so that the effect is merely a lengthening. Tendons weakened by disease or previous wear and injury frequently rupture. Ruptures are rare in persons under twenty-five years of age and usually occur in the latter half of life when the tissues are brittle and have lost their resiliency and the factors of arthritis and wear have developed. The bones over which the tendons slide may be roughened because of fracture or arthritis and cause wear and fraying of the tendon until it eventually ruptures. Similarly the stress and overuse of tendons and muscles in certain occupations may weaken them until they break. Examples are the muscles of the neck in loaders, the Achilles tendons in mountain climbers, the adductors in equestrians, the extensor longus pollicis in drum-

mers and the long head of the biceps in plasterers. Infectious diseases lead to rupture of tendons and muscles by general weakening of these structures. Other diseases act locally such as tumor, trauma, tenosynovitis, either pyogenic, gonorrheal or tuberculous, arthritis, lipoma of tendon sheath and trichinosis. Because of the lack of the sense of pain rupture may result in tubes or strangulation and from convulsions in epilepsy or tetanus.

Symptoms.—A rupture of a muscle may be so mild as to imitate lumbago or stiff neck or if greater may result in hematoma showing as a firm tender painful swelling. Several days later a sulcus can be felt across the muscle. Muscle ruptures cause a sharp severe painful snap or tear and disability, weakness and pain on movement of the muscle which is often referred to the origin or the insertion. The pain from the rupturing of a tendon is but momentary and but little swelling or pain ensues. After the rupture of a tendon or muscle the nerve is left and retracts and forms a rounded swelling or muscle belly which is extra movable, ideway and travels on contraction. The portion of the muscle separated from the nerve supply atrophies.

Treatment.—Surgical repair of the tendon or muscle should be prompt before contraction of the muscle and retraction of the tendon become organized and permanent. If for some reason this cannot be done the muscle or tendon ends should be pulled together by applying coaptation splints and the joint splinted in flexion to prevent retraction when repaired later. The regenerative ability in muscles is poor and unless close approximation of their ruptured ends is accomplished scar tissue will intervene and will later stretch out. Sutures cut through muscles so the suturing should be far back and somewhat broadened through the muscle catching the fascial matrix like where possible. Suturing with strips of fascia eventually results in firmer union. The muscle sheath also should be repaired and a gap in the muscle should be bridged by a sheet of fascial graft.

SPECIAL REMARKS

The Extensor Tendon of the Finger.—Stubbing an extended finger as with a

baseball either avulses the insertion or a small piece of bone with it causing drop or mallet finger. Immediate splinting and keeping the distal joint of the finger in extreme hyperextension and the middle joint in flexion for five weeks will remedy the condition. In such cases suturing is unnecessary. In late cases (two weeks or more) suturing is necessary even if supplying a short tendon graft. Trauma and silk sutures too frequently prevent motion by causing adhesions to the head of the middle phalanx so here removable stainless steel wire no. 35 gives better results. Where the central slip of the extensor tendon is ruptured over the middle joint of a finger resulting in a position of flexion of this joint and hyperextension of the distal joint similar treatment is required.

Extensor Longus Pollicis—Rupture primary or often delayed occurs where the tendon passes through its groove on the radius because there it is directly traumatized against the bone cut or worn by a spicule of bone from a Colles fracture or worn from use. The result is a loss of extension in the distal and partial loss in the proximal joint of the thumb so in grasping it will not clear an object. Repair is by means of a short tendon graft or by transferring one of the extensor tendons from the index finger.

Biceps Cubiti—Rupture of the biceps cubiti may occur at the insertion lower tendon musculotendinous junctures belly of the muscle tendon of the short head or long head or at the glenoid attachment. The long head is ruptured the most frequently and commonly between the tuberosities of the humerus because of wear thus differing from rupture in the other sites in being usually latent. The combination of degeneration of the tendon caused by senility roughening of the bicipital groove from arthritis and an occupation involving arm raising accounts for the frequency of the wearing, fraying and finally rupturing of the tendon at this site. Rupture of the tendon of the supraspinatus as a tear across the capsule of the shoulder joint may also be associated from impingement against the acromion. Ruptures that are not between the tuberosities occur usually in heavy work in lifting or from sudden tension on the outstretched arm.

Symptoms—In the latent cases the arthritic like ache in the deltoid region is increased by work and weakness and difficulty in arm raising are noted. If the long head becomes reattached in the groove there may be hardly any symptoms. One function of the biceps is to hold the head of the humerus into the glenoid cavity for proper mechanics. In cases of rupture especially of the tendon of insertion this action is lost and there is much difficulty in raising the arm. There is also weak flexion of the elbow and the contour in the biceps muscle and tendons changes.

Treatment—In acute cases immediate suture should be done except in rupture of the tendon of the long head in the joint. Here as in late cases the tendon is usually attached to the head of the humerus in a hole in the bicipital groove or to the origin of the short head in the coracoid process. Rupture of the tendon of insertion is repaired by direct suture to the tuberosity of the radius the removable stainless steel wire suture pressing out the dorsal skin to a button. In late cases a fascial graft is added.

Supraspinatus Tendon—Rupture of the supraspinatus tendon is prevalent after middle life and is often preceded by gradual weakness and pain as the tear in the insertion of the tendon may be gradual following impingement against the acromion. In the repair after overstrain lime is deposited in the tendon and may discharge into the subdeltoid bursa which overles it. Eventually in lifting a sudden tearing may occur resulting in pain and inability to raise the arm. Conservative treatment in mild cases is by means of an aeroplane splint. Surgical repair consists of repairing the tear in the tendon and the shoulder capsule and splinting in abduction. A mere deposit of lime is absorbed after needling by Milgram's method.

Rectus Abdominis—Rupture of the rectus abdominis may be caused by lifting and pulling. It also may occur in pregnancy and following septicemia. The local pain tenderness and rigidity may erroneously suggest an intra-abdominal condition.

Quadriceps—The usual site of rupture of the quadriceps is across the patella extending well into the tendon on each side. The cause is sudden overflexion of the knee or excessive contracture of the quadriceps.

Similarly the tendon of the quadriceps may be torn completely across just above the patella. Rupture may also occur across any part of the gastrocnemius muscle especially in the rectus or across the deep fibers only. More rarely the patellar tendon is torn from its attachment to the broad rough triangular area under the patella. In the young the tibial tubercle may be avulsed instead. The symptoms are immediate pain, swelling, effusion and loss of power to extend the knee. If the rupture is below the patella the latter rides upward when the quadriceps is contracted or the knee is flexed and if the rupture is above a sulcus is demonstrable. Treatment is by direct surgical repair uniting the patella by wire or chrome catgut sutures. The rent in the quadriceps tendon should not be overlooked. In late cases of rupture above and below the patella one must resort to fascial grafts.

Gastrocnemius—In springing off the ball of the foot a sudden pain may be felt in the calf as some of the fibers of this muscle rupture. There is local pain and tenderness and pain on standing on the ball of the foot. Treatment includes rest, local strapping and raising the heel of the shoe.

Rupture of the Achilles tendon is fairly frequent and occurs from sudden muscular strain. It may be at the musculotendinous juncture in the middle of the tendon itself or at a point just above the calcaneus or a piece of bone from the latter may be avulsed. A gap can be felt in the tendon and the belly of the calf muscles appears round and retracted upward. Dorsiflexion of the ankle is increased and power to stand on the ball of the foot is lost. Treatment is by direct and immediate suture, all paratenon and shreds of tendon being preserved as essential aids in the repair and splinting with the knee flexed and the foot in the equinus position. In late cases it will be necessary to bridge the gap between the ruptured ends of the tendon with fascial graft.

SEVERED TENDONS

The tendons in the forearm and hand are usually severed by glass, porcelain, faience, knife, huzz saws and sharp tools. If severed within a sheath the ends merely round over and remain free but if infection is present they proliferate and attach themselves

If severed within paratenon each end sends out a growth mostly from the paratenon and epitenon an inch or more in length in an effort to become reattached. The two ends may reach each other and then contract reestablishing the tendon or at least motion on the next joint or may become attached to the surrounding tissue thus hampering the action of the muscle especially a common muscle to several tendons.

Primary Repair—Before anesthetizing tests should be made for severed nerves and tendons. The tendons should not be sutured in wounds which are very dirty or highly traumatized even if seen early. In most wounds tendon repair may be done up to eight hours but if factors are favorable (clean laceration and no excess of leukocyte or bacteria in smears) it may be done up to twenty-four hours but never after that. Bacteria will have multiplied so that infection will be probable and such infections are crippling.

For tendon repair the limb should be rendered bloodless by winding with an Esmarch bandage 1 inch above this in the upper arm a blood pressure band should be pumped to 300 mm mercury and the tubes clamped. The Esmarch bandage is then removed.

After the wound has been covered the limb is shaved and thoroughly washed with soap water and benzine. The wound and limb are then painted with 50 per cent tincture of iodine and the wound is immediately blotted to prevent penetration of the chemical. The whole surface of the wound is excised with exquisite care and thoroughness all traumatized and infected tissue and all chemical being removed. It may be rinsed with copious amounts of salt solution. Retracted tendon ends may be recovered through small transverse incisions. All vulnerable structures such as joints, bones and tendons should be covered by skin flaps and the denuded areas by thin skin grafts. The tendons are sutured with a minimum of suture material, silk being used or preferably removable fine stainless steel wire. All handling of tissues should be atraumatic. The wound is then closed usually without drainage and tetanus antitoxin administered. The arm is splinted with the wrist not the fingers in flexion if flexor tendons have been severed and elevated.

Primary tendon suture from the distal part of the palm to the middle finger joints results in failure caused by adhesions unless special precautions are taken. The annular sheaths are slit laterally to allow for swelling during healing. Stainless steel wire being non irritating is used and placed in one tendon end only because a tendon pulls in only one of its ends. The two wires are passed down through the other end and on out through the skin to be anchored there to a button. A pull out wire is looped about the suture and brought out through the skin proximally to withdraw the suture backwards in three weeks when the tendon will be united. The tendon ends are either laid together or approximated with one tiny silk blood vessel suture. Absence of any suture is less irritating than is the presence of silk. The latter after three weeks is but an irritating foreign body. As a further precaution to lessen adhesions at the tendon juncture the suture may be placed at a distance proximal to the juncture as in the palm.

Late Repair—Late repair of tendons should be postponed until at least four months have elapsed since the last wound healed for fear of latent infection. All such repairs of the hand or forearm demand a more exacting technique and attention to a host of minute details than does the usual surgical procedure. Rigid asepsis and delicate handling of tissue are essential or else the subsequent tissue reaction will be sufficient to bind the tendons and prevent motion. Such operations should not be undertaken lightly and without thorough preparation as they are often unsuccessful. The problem is usually composite involving in addition to tendons nerves skin and other tissues.

The extensive cicatrix should be excised so that only good tissue remains. If there are flexion contractures of the skin this skin should first be removed and good fat lined skin substituted by means of pedicle grafts in order to improve the nutrition of the limb by relaxation and to provide mobile tissue through which the tendons can move. Joints should be mobilized before tendons are repaired and also nerves should first be sutured so that they can regain their trophic effect on the tissues. Incisions should be so

placed that they do not overlie the tendons and do not cross flexion creases at right angles. All median longitudinal incisions should be avoided lateral ones and those following the natural creases in the skin being used instead.

The pulleys or annular ligaments in the fingers and about the wrist should be reconstructed to prevent the tendons from pulling across the joint and so losing their mechanical efficiency. Tendon repair carried out after two months generally requires free tendon grafts to bridge the gaps because the muscles will have contracted and much of the tendons will have degenerated from disuse. Tendon freeing and tendon transfers are useful but direct tendon suturing can usually be done only in fresh cases. The gliding mechanism for the tendons should be reconstructed as tendons which pass through cicatrix will become scarbound. One should aim to have a minimum of moving parts and a maximum of gliding mechanism. The latter can be obtained by interposing thin fascia between the tendons and the bones or scar tissue with its gliding surface next to the tendon. Thin sheets of paratenon fat which can be obtained from over the triceps tendon or close to the fascial lata can be similarly used. Where possible it is well to transplant a tendon plus its layer of paratenon as a complete gliding assembly. The suturing or juncture of the tendon should be made at the insertion in the finger end or in the palm and forearm where adhesions will do the least harm. A juncture made within a finger will inevitably become fixed in the narrow channel. Therefore damaged tendons should be removed completely from the finger and a new part substituted by free tendon graft together with either the loose tissue surrounding its epitenon or with a sleeve of paratenon. Free tendon ends should not be left in the tissues as they will become reattached and will cause flexion contractures and loss of function.

Tendon grafts can be obtained from the palmaris longus from surplus tendons in the hand and forearm such as the sublimis and from the long extensors which reach from the lower third of the shin to the toes. The extensor brevis will continue to extend the toes. Strips of fascia may also be used as

substitutes for tendons, but these are prone to adhere. Free tendon grafts remain alive as such. Their surfaces and much of their depth subsist at first on surrounding lymph and soon acquire a blood supply of their own. Some patchy necrosis occurs within a graft but this eventually becomes substituted by normal tendon tissue. In the first three weeks the graft becomes swollen and edematous but this condition subsides and in three months the graft closely resembles normal tendon both in the gross and microscopically. Practically free tendon grafts

ing to the end with two or three stitches on one side and three or four on the other. The amount of silk showing on the surface is minimal as each needle is reinserted only a few fibers away from where it emerges. With sharp scissors the tip of the tendon grasped by the hemostat is cut off and each needle is then made to re-enter the side of the tendon and emerge from its end. There is thus a non strangling sphering effect over a length of tendon. The two strands of silk are drawn tight to remove all slack and are similarly spliced up the other tendon end which is likewise held taut by a hemostat on its tip. The two strands emerge from the same hole $\frac{1}{2}$ inch up this tendon. To slide this tendon end down against the other to eliminate slack first one strand is drawn taut and the tendon is slid down then the other strand is

FIG. 59.—Tenorrhaphy. A Tendon grasped and suture started B further steps in suture C traumatized end of suture cut off D method of making end-to-end attachment of tendon ends.

are successful and even hypertrophy to sufficient size to accommodate the strain. They show some tendency to contract, so they should be long enough to be sutured under slight tension when the origin and insertion are placed at their maximum distance apart.

In suturing tendons with silk the untreated is used or the knots slip apart. The tendon is not handled but is held taut by grasping its tip with a Kocher hemostat. A 10-inch piece of silk with a straight spear-pointed needle threaded on each end is used to splice down one tendon end and up through the other. The needles are passed diagonally back and forth through the tendon starting $\frac{1}{2}$ inch from the end and work

drawn straight and the tendon again slid down. This snugness keeps the ends from separating when under tension. The two strands of silk are tied together the single knot being sunk within the tendon at a place where it will have the least tension to avoid breaking. A little rolling fits the ends accurately together. Such junctures become invisible.

When removable stainless steel wire is used no. 34 for flexors and no. 35 for extensors it is spliced through the tendon end exactly as shown in figure 59 C but in the proximal tendon end only. The needles are then passed up the other or distal tendon end and on out through the skin for anchorage to a button, etc., as described under primary repair. The two ends of the pull-out

wire which is looped about the proximal end of the suture are threaded on a single curved needle and brought out through the skin proximally and left there. In three weeks the suture is cut off and the suture is withdrawn proximally by the pull-out wire. By this time physiological union will carry on. There are many other useful methods of placing the wire so that it is removable.

As tendons heal there is in the first week swelling with fibroblastic tissue and in the second week connective tissue bridges the gap but the union is very weak. By the end of the third week tendon strands span across and furnish moderate strength of union. Exercise up to this point is undesirable as it produces adhesions but it is advisable thereafter. During the fourth week the exercise should not be forceful. During this week the tendon loosens from its surroundings. During the first three weeks strain is prevented by splinting the wrist in flexion in the case of flexor tendons and in keeping the wrist and fingers in extension in the case of extensor tendons. Adhesions are inevitable and greatest in two weeks. Later under stimulus of active exercise more and more motion of the tendons will result. The maximum improvement possible may not be gained for a year.

REFERENCES

may be found also on the volar surface of the wrist on the volar or dorsal surface of the finger on the dorsum of the foot or of the toe on the lateral surface of the knee or in the popliteal space. It is filled with a mucoid material is usually thin walled and is found in the region of a tendon sheath or a joint capsule. It may occur even in the substance of the tendon. "Carp and Stout" believe it to be due to mucinous degeneration of the capsule of a joint or of a tendon sheath. The studies of De Orsay, Mcerry, Jr. and Ferguson³ suggest that the contents of a ganglion are mucoid rather than mucinous and that the process is one of degeneration of collagen fibers rather than a secretion of connective tissue cells.

Ganglion occurs most commonly in the second, third or fourth decade and it is not unlikely that trauma is an etiologic factor. Pain and weakness are rather common symptoms. According to Mason¹ complete excision is the best treatment. However, this must be performed in a bloodless field and by careful dissection. It is not sufficient to remove the cyst alone but the tissues from which the ganglion springs must be excised since they contain other cysts or degenerative areas which are likely to lead to recurrence. Transverse incisions are much to be preferred to longitudinal ones for removal of the carpal ganglia. The transverse incision gives excellent access and since it follows the natural skin folds heals with a minimum of scar and contracture. When the ganglion is accessible as on the dorsum of the wrist dispersion by striking it smartly with a book and massaging the extravasated contents will effect a cure in some cases. Aspiration is practically useless and injection of strong irritants is to be condemned. Sarnat⁴ has cured 78 per cent of 64 ganglions by aspiration of the bursa and injection of 5 per cent sodium morrhuate.

VIII. MUSCLES AND LIGAMENTS

SURGERY OF THE MUSCLES

The surgery of the muscles includes the following (1) congenital deformities (2) traumatic lesions (subcutaneous or open) (3) inflammations (acute and chronic) (4) muscular changes (atrophy, degeneration, hypertrophy, contracture), (5) neoplasms and (6) parasites

CONGENITAL DEFORMITIES

It is not uncommon to find cases of congenital absence of muscles. Indeed such an absence may occur on one side of the body and not on the other. Several muscles are so inconstant that their presence or absence is not regarded as abnormal and even such great muscles as the pectorales majores may be partly or totally absent on one or both sides of the body.

TRAUMATIC LESIONS

Direct and indirect forces produce traumatic lesions which may be subcutaneous or open such as contusions, partial and complete ruptures and hernias. From a pathologic point of view one may differentiate five degrees of muscle injury according to the extent of damage: (1) muscular stupor, (2) fibrillar rupture with hematitic infiltration, (3) partial rupture with hematoma, (4) complete rupture and (5) mangle.

Contusion of Muscles—The damaging force may come from without or within. Violence from without is usually due to falls, blows, kicks or bites of animals (more commonly horses or dogs). Violence from within is due to the displacement of a bone or bones following a fracture or dislocation.

The *symptoms* of a contusion are disturbed function, more or less pain when attempting to use the muscle with the maintenance of an attitude to relax it, swelling, fluctuation, ecchymosis and hematoma depending on the amount of hemorrhage which has occurred. The extent of separation of the torn ends of a muscle is commensurate with the size and length of the muscle.

The *prognosis* naturally varies. In uncomplicated contusions restoration of function is usually complete in a few days or weeks. If the nerve supplying the muscle is also contused however as frequently happens in the deltoid muscle atrophy and impairment or loss of function of that muscle occur and persist for some time.

The *treatment* at first should consist of rest by immobilization, relaxation, elevation of the affected part if possible and application of external heat followed by massage, a moderate compressive elastic bandage and graduated exercises. Occasionally the nerve may be severed. It is extremely important to be cognizant of this possibility in order to minimize the loss of function by early and adequate treatment.

Partial Ruptures (Sprains and Tears) and Complete Rupture of Muscles—These are of frequent occurrence.

Mechanism—As early as 1859 Maydl in a comprehensive article analyzed and classified the different mechanical conditions that may cause a muscle to tear and Bruckner and Milch have presented this scheme in outline form as follows:

Muscles tear as a result of

I Muscular action

1. Flaccid

1. Contraction of antagonist
2. Passive stretching

B Contracted muscles

1. Active contraction
2. Contraction of antagonist
3. Increase of tearing over cohesive power
4. Asynchronous contraction
 - a. Inner part against outer (as in bifid muscles)
 - b. Distal part against proximal part
5. Additional muscular force of another muscle

II External trauma

III Spiral twists of limb

IV Degeneration of muscle as in disease and in neurologic condition

Fig 60—These two photographs were supplied by Drs Everingham and Hitchcock. At left, partial rupture of the medial head of the left gastrocnemius muscle. The belly of the muscle protrudes even when the leg is relaxed. At right the right leg for comparison.*

Fig 61—Partial rupture at proximal musculotendinous junction of the long head of the right biceps due to direct trauma. Note the characteristic bulging of the muscle belly.

Fig 62—Partial rupture of right deltoid muscle†

Sites and Frequency—The muscles of the calf (Fig 60) come first in frequency, followed by the extensors of the leg, the biceps of the arm (Figs 61-63), the Achilles

tendon and the extensor of the thumb (Grassheim). Maydl collected reports of

* *Glaucost JAMA* 100

† *Glaucost Surg. Gynec. & Obst.* 68

sixty one cases of tears of the quadriceps muscle and fifty seven of the patellar ligament—in all 118 cases—and 103 ruptures of muscles in the upper extremity (Fig 64) and trunk. When one considers all the cases of back sprains and the so called cases of

jumpers dancers runners mountain climbers and tennis players the extensor pollicis in drum players the muscles and ligaments in and about the elbow joint in tennis players the flexors in the hip of sprinters the rectus abdominis in broad jumpers the back

Fig 63—At left the condition revealed at operation—an off a trapezioid partial rupture of the tendon of the long head of the biceps. The ruptured tendon was found coiled up like a watch spring under the upper end of the muscle. A small remnant of the tendon is seen which has prevented the ball of the muscle from dropping. At right suture of the long tendon to the coracoid process and to the upper fibers of the short head.

lumbago one must realize that many of these patients actually are suffering from tears in the deep back muscles or fascia.

Occupation often is a factor in strains, tears and ruptures of muscles. Of the greatest interest are those lesions occurring in healthy young persons as a result of indirect trauma. The neck muscles usually are affected in load carriers and packers; the biceps and triceps in pitchers and lifters; the adductors of the thigh in horseback riders; the muscles of the calf in boxers

muscles (latissimus dorsi or sacrospinalis) in golfers and stevedores.

Fatigue—Excessive fatigue may render the muscular fibers less likely to resist a sudden and forceful pull or jerk. Roth in his researches noticed experimentally a waxing degeneration of the muscular fibers when the fibers were greatly fatigued and a greater fragility caused by decreased cohesion elasticity and contractility. If the fatigue is superimposed on all pathologic or

seule changes the exhaustion and consecutive tear of the muscular fibers are produced more easily.

Symptoms—When the rupture occurs through the belly of the muscle each end retracts leaving a gap or hiatus. Immediately the intervening space becomes filled with blood which in turn is replaced by connective tissue thereby forming a bond of union between the ends. Adhesions often occur in the process of repair between the separated muscular ends and the adjacent structures. Often if the rupture of the muscle or tendon is only partial the patient complains of weakness and pain in the nearby joint. If the rupture is in the upper

Fig. 64.—Rupture of the triceps brachii in a young man.

end of the biceps he may complain of pain in the shoulder; if in the lower end of the biceps of pain near his elbow joint; if in the muscles of the thigh of pain in his knee. Because of joint pain a patient is often given physiotherapy for months as the attending physician considers that there is a strain of the joint.

Diagnosis—The clinical features are usually characteristic and the diagnosis is not difficult, yet a large number of these cases go unrecognized and untreated for weeks and often months. Suspicion of a ruptured muscle should be aroused immediately when a person complains of having felt a sharp pain during a forceful muscular act of having

heard a sharp snap, often audible several feet away, of having had the sensation of being struck with a whip and having felt something give way. Immediately the limb becomes weak and often powerless. At the site of the rupture there is tenderness and sometimes swelling and ecchymosis. Often a gap can be palpated.

Treatment—If the tear is not extensive the limb should be put at rest and immobilized two or three weeks until union has occurred, then massage and graduated exercise should follow. Partial ruptures of the biceps should be immobilized in gentle flexion; those of the calf of the leg should be immobilized by the application of adhesive tape and the person should wear high heels for several weeks. If the rupture is complete or extensive immediate surgical intervention and repair are indicated. Early operation with approximation of the severed ends by mattress sutures reinforced if necessary by a piece of fascia from the fascia lata usually will give most gratifying results. If the operation is delayed for weeks or months it is not so satisfactory because of adhesions and the retraction of the ends of the muscle.

Hernia—A true muscular hernia is produced by the bulging of a part of an intact muscle through an accidental opening in the fascia. This condition is rare and usually has a gradual onset, being the result of a rent in the fascia.

A pseudomuscular hernia is produced by the bulging of an intact or ruptured muscle through its sheath. This condition occurs frequently, is of sudden onset and is accompanied by sharp pain.

Diagnosis—Aside from the slow onset the tumor of a true muscular hernia decreases or disappears when the muscle is actively contracted or passively extended while that of a pseudomuscular hernia increases.

Treatment—A true hernia requires surgical intervention only if it causes inconvenience. Incision and repair of the rent usually suffice with occasional excision of the herniated portion (partial myectomy). A pseudohernia always should be repaired.

Open Injuries—A damaging force may produce an incised, lacerated, contused or penetrating wound. The prognosis and treat-

ment of these wounds are dependent on the extent of the injury, the presence or development of inflammation and the degree of functional disturbance. The more contused the edges, the more probable is the development of infection. Superficial punctured or gunshot wounds usually heal promptly unless foreign substances are carried deep into the tissues. Then they become the most serious of wounds. Such wounds should not be probed. Recent clean wounds should be sutured in layers. An untreated wound seen for the first time after several days should not be closed but should be treated as a contaminated or infected wound. Severely contused or mangled wounds should be debrided thoroughly. The use of chemotherapeutic agents (sulfonamide, penicillin) is of advantage not only for combating infection but also for its prevention. Adequate immobilization of the injured area is always of paramount importance.

Myorrhaphy or suturing of a muscle follows the same surgical principles as mentioned under the treatment of rupture of muscles. A *cicatrix* may form in an unsutured muscle wound which because of pain or disturbance of function may require excision and secondary suture. *Partial myectomy* is a procedure performed occasionally, for example, the excision of two thirds of the sternomastoid muscle for the relief of severe torticollis. *Myoplasty, muscle lengthening and transplantation* find an increasing usefulness in the correction of deformities and defects.

INFLAMMATIONS (ACUTE AND CHRONIC)

Acute myositis may be primary (traumatic) or secondary (infective). The former follows an open wound or instantaneous injury of the muscle, and the latter is usually consecutive to a focus of infection near or distant. The myositis may be circumscribed or diffuse. Infective myositis, especially if of hematogenous origin, may be serious and usually ends in suppuration. The local symptoms are related to the muscle or muscles affected and the general symptoms to the type and extent of the myositis. If infective, the symptoms depend on the virulence of the organism. If suppuration occurs, then adequate incision and drainage parallel to the muscular fiber

should be performed otherwise rest, heat and later physiotherapy are essential in the treatment.

Fibrositis, commonly known as *muscular rheumatism*, accounts for conditions referred to as lumbago, stiff neck, pleuritic pain, and so on. Pathologically it is explained on the basis of an inflammatory hyperplasia of the connective tissue. The onset is sudden and the pain is severe and intensified by movements of the affected part. The muscles involved become swollen, spasmodic and tender to palpation and gradually contract. This condition often follows trauma, such as a sprain or contusion or exposure to cold, but frequently it proves to be a subfocus of infection in the tonsils, prostate or other sources. Removal of the primary focus, heat, deep massage and gradual stretching of the contracted muscles usually improve the condition. Attention should be directed to a bland diet, forcing of fluids and regulation of the bowels. At first it is often necessary to resort to salicylates or even morphine to relieve the pain. Daily exercises afterward will often prevent a recurrence.

Chronic myositis may be simple or specific. The simple may be fibrous or osseous. The *fibrous type* usually follows an acute myositis or is found around chronic inflammatory lesions (ulcers of the skin, osteomyelitic sinuses, and so on). The muscles are indurated and grayish in color and their fibers are overwhelmed by the connective tissue proliferation.

The *osseous type*, myositis ossificans, may be partial and circumscribed (osteoma) or progressive and generalized. The former is the result of a single or repeated trauma. Its development is very rapid. It may be localized at first only in the muscle and aside from its induration give little inconvenience. The osteoma may become attached firmly to the underlying bone, thus greatly impairing the function of the limb and producing pain. The usual sites are the deltoid and the pectoral muscles in infants; in men, the brachialis following dislocation of the elbow, the abductor longus in horseback riders, and the vastus lateralis following a kick. When the osteoma is painful or when it impairs function, it should be excised.

Progressive ossifying myositis is due to an infiltration of osseous substance into the connective system of the muscles tendons and aponeuroses. At first there is an embryonic infiltration of the connective tissue and then a fibrous induration which ends in ossification. This is a rare condition of unknown etiology (probably infective) which mostly affects males and which at first is limited usually to the muscles of the neck, back and thorax, later extending to the muscles of the limbs. The disease advances by exacerbations until all the striated muscles of the body are involved even those of the jaws and the unfortunate victim usually dies of an intercurrent disease. Because of the progressive nature of the condition treatment is unsatisfactory. At most amputation which interferes with function or is painful should be divided or should be entirely removed.

Chronic specific myositis includes tuberculosis, syphilis and actinomycosis of the muscle. Tuberculosis is rarely primary or hematogenous in origin, most often it is secondary, being due to direct extension from an adjacent tuberculous structure usually from a bone or joint. One may find an indurated mass in the belly of the muscle due to a dissemination of nodules or central caseation may occur and later large abscesses with discharging sinuses may form.

Syphilitic myositis usually occurs in the secondary and tertiary periods. In the early secondary stage there are dull nocturnal pains in the muscles of the neck and back; in the late secondary period contractures of the biceps and hamstrings occur which gradually interfere with full extension of the elbow and the knee. In the tertiary stage individual muscles are the seat of the interstitial or sclerosing type or of gummatous. These later on either undergo fibrous transformation or softening and ulceration. These affections yield readily to antisyphilitic treatment. For the contractures surgical treatment may be necessary.

Actinomycosis may involve muscles as well as other structures and when possible the entire affected area should be excised thoroughly. Iodids in large doses are often considered to be beneficial.

MUSCULAR CHANGES (ATROPHY, DEGENERATION, HYPERTROPHY, CONTRACTURE)

Atrophy of muscles arises from disuse, from overwork, from trauma, from prolonged pressure from interference with the circulation or from central or peripheral lesions of motor nerves.

The muscles become smaller and flaccid. Their functional power decreases slowly or rapidly and atrophy may progress to the complete loss of contractile substance. The anatomic alterations vary and depend on the etiology. In atrophy due to nonuse the fibers though smaller in size are normal in structure and appearance. In atrophy resulting from interference with the nerve supply the fibrils degenerate into granules of fat which later on are absorbed and the whole muscle is transformed into fibrous connective bands which finally produce the deformed and permanent attitude of the parts.

Degeneration of muscles may be fatty, the result of atrophies due to central or peripheral lesions or may follow infectious diseases such as typhoid fever. Other forms are granular, calcareous and pigmented. Treatment consists of elimination of the etiologic factor producing the atrophy or degeneration followed by electrical stimulation and physiotherapy.

True hypertrophy of the muscles is the result of the increased use of the muscles and an increase of their fibers. In pseudo-hypertrophy although the volume of the muscles is increased their strength is nil because the fibers have been replaced by fat or connective tissue.

Contracture of muscles occurs after most injuries if a group of muscles remains for some time in a state of flexion or following an inflammation in the muscle itself or lesions of its nerves. Heat, massage and gradual and prolonged stretching are usually beneficial; occasionally stretching and breaking up the adhesions under anæsthesia is necessary. Surgical intervention (muscle lengthening, etc.) may be indicated as a last resort.

Paralytic contractures, especially those following anterior poliomyelitis, should be prevented by keeping the limbs in the most favorable positions using artificial means.

if necessary, and physiotherapy to improve the muscle tone.

Volkman's contracture, often spoken of as ischemic myositis and as ischemic muscular atrophy, was first described by Volkman in 1872. While it is usually thought of as a sequel to injuries about the elbow resulting from interference with the blood supply from splints, casts or bandages too tightly applied, it occurs elsewhere and also in the absence of constricting bandages sufficiently frequently to indicate that its common site in the forearm and the factor of constriction are to be considered only as associated factors. Ischemia of the affected muscles resulting in necrosis with later fibrosis of the muscle fibers produces an apparent shortening of the flexor tendons. The factors initiating the ischemia are not completely and clearly defined. According to Leriche, an arterial lesion such as occlusion by embolus or spasm produces muscular ischemia resulting in a limited area of necrosis. While venous stasis, swelling and extravasation of blood especially beneath the lacertus fibrosus or brachial fascia may be considered as contributing factors, they are not necessary for the initiation of this condition.

Symptoms—This syndrome usually has a rapid onset. Occasionally a few hours after the initiating injury, one finds paralysis with the fingers held in flexion. The pain may be intense and should lead to an early diagnosis, but unfortunately this may be absent and the condition is not recognized until late. Decrease in the circulation to the fingers and absence of the radial pulse are more valuable signs as they are likely to be noted earlier if watched for. Later one finds a marked wasting of the forearm and the muscles are indurated and tender. The interphalangeal joints are flexed strongly when the wrist is extended and may be straightened only by flexing the wrist. The hand is pronated and the forearm flexed. Trophic changes of the nails and ulcerations from pressure points may be found.

Treatment—The best treatment is of course prophylactic. This consists of being careful to assure an adequate circulation to the forearm and hand. Careful manipulation of the fracture and the application of properly fitting splints or bandages and their

early removal in the event of any evidence of interference with the circulation are important for often only a few hours is sufficient for the beginning of this syndrome. Leriche emphasizes the necessity for early intervention. If there is evidence of a decrease in the volume of the arterial pulse at the wrist as measured by an oscillogometer the brachial artery and its bifurcation should be exposed. Griffiths and Forie agree with the concept that the initiating factor is a decrease in arterial blood supply to the muscle. Treatment is therefore directed toward restoration of the circulation through the artery and its collaterals by means of resection of the injured torn or spastic artery, periarterial sympathectomy, cervical sympathetic block or injections of acetylcholine. After the condition is well established treatment is not very satisfactory. This consists of an attempt to restore function by means of physiotherapy or by means of corrective operations.

NEOPLASMS

The majority of tumors grow from the connective tissue of the muscle. They may be primary or secondary, benign or malignant. Primary benign tumors (fibroma, lipoma, angioma, etc.) are rare and usually benign. Primary malignant tumors (sarcoma) also are found. Secondary tumors are the sarcoma and the carcinoma and originate by metastasis or from propagation from neighboring structures. A tumor of this type forms a localized swelling under the fascia in the muscle which becomes fixed and firm when the muscle contracts and soft and movable laterally when it relaxes.

Benign tumors which produce symptoms should be excised; otherwise they will enlarge and cause atrophy of the muscular fibers. When the tumor is malignant then the entire muscle or group of muscles with adjacent tissue should be removed and examined microscopically. Frequently amputation of a limb is found to be necessary.

PARASITES

Three parasitic diseases of muscles are encountered. 1. Cysticercosis is a rare disease now that meats are subject to sanitary inspection and the treatment of tapeworm is so improved. The cystic nodules may be

the size of a pea or cherry and occasionally of a hazelnut. The affected muscles become weak and painful.

2 Trichiniasis or trichinosis, is produced by the *Trichina spiralis* contained in infected meats usually pork which has not been thoroughly cooked. The parasites become encapsulated in the muscles and may or may not produce local symptoms of muscular pain, swelling and tenderness. The functional disturbance is in relation to the muscles involved. In cases of cysticercosis and trichiniasis the nodules should be excised and constitutional treatment instituted.

3 Hydatid cysts are caused by the *Tænia echinococcus* the sites of election being the liver and lungs rarely the muscles. When they are found in muscles treatment consists in excision of the entire cyst great care being taken to avoid leakage of the contents and consequent dissemination of the disease.

SURGERY OF THE LIGAMENTS

CONGENITAL DEFORMITIES

Since a portion of the human body may be congenitally absent one cannot doubt that this applies also to ligaments. In order to determine the congenital absence of ligaments it will first be necessary to decide what is to be meant by that term. One now speaks of true and false ligaments but there is no agreement regarding the matter. Even if one excluded such highly variable structures as the so-called transverse humeral and scapular and the glenohumeral ligaments it would still be true that there would be great variability. This applies especially to ligaments which are merely thickenings of the deep fascia such as the volar and dorsal carpal and the transverse and cruciate carpal ligaments and the inguinal ligament. There also is great variation in ligaments associated with some of the great joints such as the hip joint even if one excludes the retinaculum of the femur. Moreover it is not uncommon for the round ligament of the head of the femur to be absent though it is doubtful whether it ever is congenitally absent except perhaps when the entire femur is not present.

As the structure of ligaments is so similar to that of tendons the operations on them follow the same general principles and therefore will be considered only briefly in this chapter.

TRAUMATIC LESIONS

Sprains—By a *sprain* is meant the aggregate of the various lesions which are produced in and about a joint whenever its movements are carried beyond the normal range or in some direction in which the range is very limited. Muscles play an important role in supporting joints and therefore if sudden violence occurs when the muscles are relaxed or at a disadvantage a sprain is produced if the force is sufficient a sprain fracture or even a dislocation may occur. Joints with an extensive range of motion such as the shoulder or the hip are less subject to sprains but more prone to dislocation.

The causes of sprains are direct and indirect depending on how near the joint the trauma acts. Predisposing factors are previous sprains certain deformities (such as pes planus or genu valgum), muscular atrophy and acquired or congenital relaxation of the ligaments. In order of frequency sprains occur in the ankle, knee, wrist, elbow and spine.

The lesions of a sprain may involve many of the structures surrounding the joint, and the extent of the damage depends on the intensity of the trauma. A ligament which is stretched suddenly may tear, it may rupture at its point of attachment or it may even avulse a piece of bone of varying size (sprain fracture). Intra-articular cartilages may be displaced or torn as in the knee. Periarthritic lesions also occur such as overstretching and tearing of muscles or tearing or displacement of tendons and ecchymosis of the subcutaneous tissue. The synovial membranes may be torn with formation of a hemarthrosis. Very important is the muscular atrophy which follows a severe sprain with synovitis and effusion (such as is seen in lesions of the knee with consecutive reflex atrophy of the quadriceps muscle which greatly prolongs the disability). In a sprain the lesion may extend from the joint primarily affected to nearby and distant joints as often occurs in cases of sprained ankle in

which the joints of the foot are often involved

Symptoms are pain swelling ecchymosis limitation or impossibility of movements of the joint At first the pain is sharp and severe and later becomes a dull deep ache Palpation elicits tenderness along the joint line or over the insertions of the torn ligaments There is also cutaneous tenderness caused by the sprain of the underlying muscles

The *diagnosis* of an uncomplicated sprain can be reached only after the elimination of laceration of important ligaments luxation epiphyseal separation and articular fractures In rupture of important ligaments there is abnormal mobility such as lateral movement in the elbow or knee In luxation the articular cavity is empty the displaced bone is in an abnormal position and there is an impairment of the function of the limb Since many sprains are often complicated by fractures it is always wise to have roentgenograms taken (In sprains in the young there may be fractures of the cartilages which the roentgenograms do not reveal and can be diagnosed only by palpation hence the x ray should supplement and not be substituted for one's tactile sensation)

Prognosis—Gradually the blood and synovia are absorbed and the lacerated ligaments reunited As healing occurs adhesions often form in the joint or in the surrounding tendon sheaths If an uncomplicated sprain is treated early and effectively recovery is obtained in a few weeks

Treatment—Early cure is important Limiting the motion of the joint by adhesive or elastic bandage will do much to prevent effusion into the joint If marked effusion does occur aspiration may be indicated Elevation of the joint tends to lessen the swelling and pain as does an evenly applied and snugly fitting dressing Heat effluvia and later massage help to accelerate absorption and restore function Early movement should be encouraged especially in sprain of the ankle unless there is evidence of gross tearing of the ligaments Decided encouragement for early function is afforded by the injection of novocain as suggested by Leriche directly into the areas where tenderness is elicited The patient is al-

lowed to walk about and if pain recurs the injection may be repeated Active use of the ankle tends to decrease the swelling and stiffness about the injured part and promote early healing

Syndesmotomy—Ligaments may be severed in accidental wounds or as an incident in operations on the joints or spine In either event the repair should be executed accurately with strong but not too heavy chromic catgut kangaroo tendon or fascial strips

Shortening or lengthening of ligaments may be necessary occasionally in order to correct deformities due to disease

Rupture of Crucial Ligaments—One should consider the probability of rupture of the anterior crucial ligament after a severe sprain of the knee whenever there is hemiarthrosis, hyperextension is possible with the knee completely extended there is internal rotation of the leg at the knee if the head of the tibia can be slipped forward on the femur or if there is a lateral mobility that is a lateral abduction (lateral rocking) with the knee in the semiflexed position Usually associated with this lesion is damage to the internal lateral ligament and even displacement of the internal semilunar cartilage Rupture of the posterior crucial ligament is to be considered if when the leg is fully flexed the head of the tibia can be slipped back on the femur

If the tibial spine has been avulsed and a chip of bone torn from the femoral condyle this will be seen readily in the roentgenograms

Considerable pain will be present as a result of distention of the joint capsule with blood Immediate aspiration under the most aseptic conditions will afford great relief If only the crucial is torn complete immobilization in a cast over a long period will suffice If there has been rupture of the internal lateral ligament also only arthrotomy and repair will effect a cure This is best accomplished through a long midline incision which curves to the inner border of the patella

IX. THE BURSAE

DISEASES OF AND INJURIES TO BURSAE

Bursae exist in large numbers in the body usually as cavities lined with serous or endothelial cells which secrete fluid and permit the ligaments muscles skin and other structures to move freely and with a minimum of irritation They vary in situation size and structure they may be adventitious and may develop from occupation or other forms of irritation such as that resulting from deformity of the spine with kyphosis as in tuberculosis or from the constant rubbing and pressure of tight shoes on the head of the first metatarsal bone Any bony prominence subjected to constant and forceful movement is capable of forming such a protective space Bursae may enlarge as do the more or less constant bursae and become filled with serous fluid blood or loose bodies or become infected and contain pus As many of these bursae lie in proximity to joints and attachment of muscles it is common to find that they are contiguous with and at times really an outpouching of the synovial membrane As a rule the deep bursa is the more constant its size varies somewhat with the patient's occupation and activities and it is subject to the same diseases as the joint with which it is connected When bursae become distended they are called bursal cysts or hygromas The superficial bursae are the most commonly infected and knowledge of their situation is often most useful in distinguishing bursitis from intra articular disease such as synovitis and septic arthritis In one instance an infected prepatellar bursa resulted in infection of the knee joint when the physician under the impression that he was dealing with a distended and infected knee forced an aspirating needle through the infected bursa and into the knee joint Unjustifiable economic loss and prolonged disability with pain result from failure to recognize the inflammatory lesions affect ing deep bursae The physician must be

constantly on the lookout for these diseases and injuries remembering the anatomic and physiologic relation of the bursae to the patient's occupation and the fact that bursae are subject to trauma inflammation rheumatism gonorrhea syphilis tuberculosis neoplasms and gout

Bursitis may be classified as acute or chronic traumatic or infectious and syphilitic gouty or malignant

PATHOLOGY

The reactions of bursae are similar to those of the synovial membranes There is first an increase in the formation of fluid and distention of the fibrous sac Later the bursal wall becomes edematous degenerated and thickened If the irritation causing the reaction continues symptoms of pressure will occur as the surrounding tissues are compressed motion of joints may be inhibited because of pain Traumatic bursitis may become infected bursitis and result in a local rise in temperature and edema of the extremity As the bursitis continues the lining membrane may form villi or adhesions may form multiple cysts Pedunculated masses with enlarged tips may hang into the sac in which case movement may cause a grating sound The masses sometimes break off and result in loose bodies and at times form cartilage If the bursa is in the region of a joint adhesions result in its partial obliteration and limitation of motion This is commonly seen in cases of subacromial bursitis Calcified masses often appear to exist in bursae but at operation they are found more often in the surrounding tendons or capsule In cases of long standing the wall may be many times the normal thickness and as a result of prolonged irritation and degeneration a fibrous fatty or even calcified hygroma may follow Infected bursae distend with pus and either penetrate the soft tissues to come to the surface or rupture Tuberculous bursae are as seen in the greater trochanter often secondary to involvement of bone and may

contain many rice bodies although the presence of the latter is not pathognomonic. Syphilitic bursae usually form during the tertiary stage and are prone to cause the formation of sinuses. Neoplasms of bursae are factors the surgeon takes into consideration. Chondromas and fibrosarcomas are the most frequent and the prepatellar bursa is the one usually involved.

TREATMENT

The type of bursitis whether it is traumatic infections, septic, tuberculous or syphilitic, its chronicity and its situation are factors the surgeon takes into consideration in determining the course to be followed.

Traumatic Bursitis—In ordinary cases caused by trauma, relief usually follows rest of the parts affected; thus housemaid's knee responds when diagnosed early to avoidance of the kneeling position. When the irritation of the bursa is kept up as is often the case among scrubwomen and nurses the bursa assumes a cystic appearance from distention with fluid and a hygroma forms which resists conservative treatment and may fail to disappear. Rupture of these traumatic sacs is often sufficient to effect a cure. When the bursa is superficial this may be accomplished by firm pressure of the thumb. Aspiration of fluid and application of a firm bandage are often successful. Aspiration followed by repeated injection of an antiseptic solution such as metaphen or half strength tincture of iodine which causes irritation and stimulates or destroys the lining is common practice. As the bursae are at points of pressure and act as bearings, traumatic bursitis should, if the patient cooperates properly, respond to rest or aspiration if not, and should the bursa become chronically enlarged, excision is justifiable and assures cure. The injection of saline or of procaine solution into a traumatic bursa which has resulted in a stiff and painful joint may give instant relief. A large distended hemorrhagic hygroma is best excised.

Infectious Bursitis—Infectious bursitis is often multiple and should be treated by removal of the primary source of infection. The teeth, tonsils and other common sources of infection must be eliminated, the parts involved must be put at rest and heat must

be used. Should the inflammation continue to cause enlargement of the bursa, aspiration may be useful. The value of removal of foci of infection in multiple bursitis is illustrated in the following case.

Case 1 A man about twenty years of age complained of enlarged and painful swellings at the shoulders and knees. Examination disclosed the subdeltoid and suprapatellar bursae to be distended with fluid. A diagnosis of infectious bursitis was made as the movements of the joints were free and the joints themselves were not distended. Following removal of infected teeth and tonsils and the use of physiotherapy, complete relief was obtained and the swellings subsided.

Infected bursae (septic bursitis) require drainage; this should be done early to prevent the lesion from becoming chronic and causing secondary involvement such as septic arthritis or edema and to avoid unnecessary loss of time in recovery. Should the drainage continue over a long period the bursa may be safely excised and the wound drained for a short time. In bacterial infections caused by streptococci, staphylococci, gonococci and pneumococci, the use of sulfamidazole or sulfapyridine may be of value. Penicillin is proving useful in the treatment of some bacterial infections.

Tuberculosis of the bursae is often secondary to an underlying focus in the bone. Careful search for a primary source such as pulmonary tuberculosis is imperative and treatment should be directed along general antituberculous lines as well as toward the elimination of the affected bursa and the underlying focus in the bone. Drainage and aspiration are of little use. The treatment of choice is excision followed by the use of heliotherapy, cod liver oil and other remedies to build up the patient's resistance.

Syphilis of bursae is rare and occurs in the tertiary stage; it tends to chronicity and the formation of sinuses. The use of diagnostic laboratory tests and adequate antisyphilitic treatment are advisable before resorting to surgical operation.

Gouty bursitis is characterized by chronic inflammatory changes and chalky deposits in the tissues, pain and remissions from symptoms. In the writer's experience the adventitious bursae of the great toe and the olecranon are most frequently affected.

Under treatment by heat, diet and, in rare instances, excision, pain and swelling are relieved.

PROGNOSIS

When a diagnosis of bursitis is made early and the etiological factor has been ascertained as being traumatic, the prognosis is usually good. If there is evidence of hemorrhage into the sac and aspiration or drainage is done early, the prognosis is likewise favorable. Rest of the extremity is important in obtaining prompt recovery; if the bursa is irritated by constant movement, the inflammation is continued, and further distention of the sac results. The longer irritation continues, the more difficult and

this may require considerable dissection. As a rule, aspiration in the early cases and excision in the more chronic cases, in which the bursa has become infected, are the best methods of treatment. A virulently infected bursa, however, should be drained; if the discharge continues, it can be excised later with safety.

BURSAE OF THE SHOULDER

Bursae of the shoulder (Fig. 65) are of considerable interest; of these, the subdeltoid, or subacromial, bursa is the one most commonly affected. It is a large, constant bursa which lies beneath the deltoid muscle and over the capsule of the shoulder joint

Fig. 65—*a*, Relation of subdeltoid bursa to supraspinatus muscle. *b*, Situation of the bursa during abduction of the humerus.

prolonged the recovery. The physician should therefore obtain the cooperation of the patient, especially in cases in which deep-lying bursae are likely to cause prolonged disability, because, when the bursitis has existed for some time, rest will necessarily result in greater economic loss than is usually required to obtain relief. A patient who has not cooperated properly or whose condition has been incorrectly diagnosed is the one who finally comes for relief when surgical operation is the only alternative. Then, aspiration is often repeated, only to have the bursa promptly refill. Incision and drainage may then result in prolonged and irritating discharge. Thus, the patient faces the necessity of having the bursa excised, and

and may connect with the bursa of the coracobrachialis muscle. Subdeltoid, or subacromial, bursitis causes pain, localized tenderness and limitation of movement of the shoulder joint. It is often confused with periarticular arthritis and rupture of the supraspinatus tendon. The calcareous deposits which are seen in roentgenograms are usually found to lie beneath the bursal sac, in the ligament. When the bursitis does not respond to conservative treatment, resort may be had to manipulation, with the patient under anesthesia, or to excision. The loose bodies and the calcareous deposits may be excised; the latter, however, are often absorbed under the influence of local use of heat and massage. Inflammation of

the subdeltoid bursa is not easy to diagnose correctly because the other anatomic structures about the joint are also affected by trauma and arthritis. Codman has done a monumental work on the subject and the student is referred to his book on the shoulder. The subscapularis bursa between the subscapularis muscle and the capsule is con-

sidered. The method has also been employed successfully by Patterson and Darrach—Ed.]

Case 2 A housewife aged forty-eight, complained of swelling of the right shoulder (Fig. 66) and of pain in the thorax of ten years' duration. Two years before admission stiffness of the shoulder with pain on motion of gradual onset had appeared without recogniz-

Fig. 66.—Bulging of the right subdeltoid bursa

neeted with the joint. Other bursæ to be considered about the shoulder are the subcutaneous acromial bursa and the bursæ of the infraspinatus, latissimus dorsi, pectoralis major and the long head of the biceps brachii muscles. In the treatment of abnormal conditions of these bursæ the position of abduction and external rotation pre-

able injury. A year later after severe exertion sharp excruciating pain had developed also a swelling had appeared which had increased in size. The pain in the thorax had seemed to bear a relation to the swelling in the shoulder; it had become worse when the patient noticed more swelling following exertion. She also complained of urinary frequency, tenesmus and nocturia and remembered that she had passed blood when twenty-five years of age.

On examination the patient was found to be of more than her usual weight; the pulse rate was 64 and temperature 98.2° F. The systolic blood pressure was 80 mm. of mercury, and the diastolic 64. Some rales were heard over the right side of the thorax. A large, soft tumor was present anteriorly over the right shoulder and had the feeling of containing rice bodies. The supraclavicular lymph nodes were palpable and hard. Urinalysis repeatedly revealed traces of albumin, occasional erythrocytes and occasional pus cells. Roentgenograms of the right shoulder were negative as were those of the thorax, stomach, kidneys, ureters and bladder. Roentgenologic examination of the spinal column gave evidence of spondylitis. Urologic examination including injection of guinea pigs with material from both kidneys was negative. The Wassermann reaction of the blood was negative and results of the blood count were within normal limits. The bursa was aspirated and a cloudy, milky fluid was obtained. The patient made a gradual recovery.

Case 3 A school teacher aged forty-two complained of severe, almost unbearable pain in the right shoulder. The onset had been gradual and pain and partial disability had continued; pain had been noticed later in the fingers and toes. Her father had been afflicted with rheumatism.

On examination there was definite atrophy of the musculature of the shoulder, local tenderness over the bursa and limited abduction and rotation, especially internally of the shoulder joint. Urinalysis, blood count and Wassermann reaction of the blood were negative.

Fig. 67.—Large calcified subdeltoid bursa

vents shortening of muscles, stiffness in abduction, adhesions and the necessity of subsequent manipulation.

[An important contribution to the treatment of acute subdeltoid bursitis is the needling method of Alanson Weeks. Under local or general anesthesia the firm-walled sac is punctured in numerous places with a bur-

Evidence of peritonsillar infection of the teeth was found. The tonsils had been cleanly removed. Roentgenograms of the right shoulder disclosed calcified masses; those of the thorax, wrists and fingers were negative. Opera-

tives were commenced and foci of infection were removed. The patient improved rapidly and was released to continue treatment at home. She made an excellent recovery.

Fig. 68.—Bilateral subacromial tuberculous bursitis: a, before operation; b, three and a half years after operation.

Fig. 69.—Specimen showing rice bodies removed from right shoulder at operation in case 6.

tion was performed and the masses were found beneath the bursa and excised; they consisted of cheesy, white material which the pathologist reported to be inflammatory tissue containing calcium. Massage and

Case 4. The right breast of a woman aged forty-five was removed for chronic cystic mastitis. While in the hospital she complained of soreness in the left shoulder which had troubled her for several months.

as well as of limitation of motion. At operation a calcified mass was removed from just beneath the bursa (Fig 65), this was $\frac{1}{2}$ inch (1.27 cm) in diameter and $\frac{1}{4}$ inch (0.6 cm) thick. The pathologist reported that the specimen consisted of cartilage and calcium. Convalescence was uneventful.

Case 5 A woman, aged fifty-six, complained of pain and tenderness in the right shoulder, with limited motion in abduction. A calcified subdeltoid bursa was found. Treatment consisted of baking and massage, with graduated exercises. The patient was principally concerned about a toxic goiter and partial thyroidectomy was performed. While under treatment, the pain in the shoulder was relieved and she was dismissed to continue conservative treatment at home. The calcified masses may entirely disappear under treatment with such physiotherapeutic measures as heat, diathermy, massage and exercises.

Case 6 A laborer, aged thirty-seven years, registered at the Mayo Clinic on Feb. 4, 1935. He stated that he had first noticed enlargement of the right shoulder about six years previously, and about a year and a half later the left shoulder had begun to show evidence of involvement. His trouble gradually increased until he was unable to abduct the arms fully, but he had continued his work up to the time of his admission.

Examination showed a semifluctuant bursal hygroma which crepitated (Fig 68). At operation on February 7, the subacromial bursae were excised and found to contain numerous rice bodies (Fig 69). The left bursa was much larger, as were the rice bodies contained therein. The result was excellent and when the patient was seen three and a half years subsequently, there was no sign of recurrence.

OLECRANON BURSAE

At the elbow the olecranon bursa is commonly affected. The condition is called miner's elbow because of the constant pressure and trauma entailed in this occupation. The swelling beneath the skin and the olecranon process is, as a rule, painless unless infected. It responds readily to treatment. The so-called tennis elbow, radioulnar bursitis, epicondylitis and epicondylalgia afflict those who follow some occupation which requires the use of a hammer or athletes who play such games as tennis. Pain in the elbow; tenderness over the radioulnar joint, which is aggravated by continued effort; pain on lifting and closing the clenched fist and flexing the wrist; dropping of objects held in the hand, and weakness of the forearm are the common symptoms. Roentgenograms are negative. The essential pathologic change is inflammation under the conjoined tendon, and a bursa is found which may be removed if rest does not relieve the condition. Bursae may form about

the epicondyle and in the triceps brachii as well as in front of this muscle, but they are not commonly involved.

Case 7 A salesman had fallen on his elbow four years before he came to the clinic. Two years after the accident the bursa had enlarged and then had disappeared. The enlargement had recurred later without evident cause. The bursa was excised and the patient had no further difficulty.

Case 8 A farmer, aged thirty-four, had sustained injuries to the tip of the elbow two weeks previous to admission, with resulting swelling and moderate pain which had persisted. The roentgenograms were negative. The condition gradually subsided with conservative treatment.

An injured bursa, such as the one reported in case 8, as a rule, does not cause much complaint unless it becomes large or infected, after which it causes considerable trouble because of the bruising of the bony prominence and irritation of the ulnar nerve. When a bursa fails to subside under strapping and rest and continues to cause symptoms, excision is usually best.

BURSAE ABOUT THE HIP

Bursae about the hip are numerous; Spalteholz has described sixteen bursae, and other authors have reported additional ones. The important ones are the iliopectineal, between the common tendon of the psoas major and iliacus muscles and the joint with which it may connect; the subtendinous, between the common tendon of the psoas major and iliacus muscles and the lesser trochanter, the ischiogluteal, between the tuberosity of the ischium and the gluteus maximus muscle, and the bursa over the greater trochanter and the gluteus maximus muscle. The principal diagnostic aid in distinguishing bursitis from disease of the hip joint is the fact that in bursitis the motion of the joint is not restricted, or is restricted only in one direction, whereas in disease of the joint the motion is painful, restricted in all directions and accompanied by muscular spasm. As the iliopectineal bursa may connect with the hip joint, it is obvious that infection affects both, and the position of comfort would be in flexion of the hip. In tuberculosis the cold abscess may present anteriorly, because of the position of the bursa. If only the bursa is affected, the position of internal rotation or extreme ab-

duction will produce pain. Swelling of the extremity may occur in iliopsoas bursitis with infection, and the bursa may be mistaken for hernia. It is common for the bursa about the greater trochanter to be affected in tuberculosis. This is particularly common when the bone itself is involved. I have reported a series of nineteen such cases, and in 73 per cent evidence of tuberculosis was found in other parts of the body.

Case 9 A farmer's wife had fallen downstairs and injured her right hip about five months before she came to the clinic. There had been ecchymosis and swelling over the greater trochanter and pain down under the outer side of the thigh. She had not been able to sleep on her right side and had felt better when at rest, although she had been able to walk. Three months after the accident, when she was rubbing

find that they are unable to sleep on the side affected. The pain usually extends down the outer side of the thigh. The patients are incapacitated by the pain but have free motion of the hip.

BURSAE ABOUT THE KNEE

The common bursa involved about the knee is the prepatellar bursa, situated between the skin and the patella. When it is subjected to trauma or infection, the condition is known as housemaid's knee. It is seldom painful, and it responds readily to treatment if the patient avoids further injury, otherwise, aspiration or excision is indicated. The deep infrapatellar bursa lies between the tuberosity of the tibia and the

Fig 70—Bilateral prepatellar bursitis in a farmer, aged forty years

Fig 71.—At the left: Multiple loose bodies in an anserine bursa, about 5 cm in transverse diameter, which was removed unopened from the region in front of the left knee joint. At the right: Large osteocartilaginous body resulting from osteochondritis dissecans removed from the left knee joint, where it had caused symptoms of locking

the region of the hip because of continued soreness she had noticed a tumor; this had increased in size and had caused a great deal of discomfort.

On examination a tumor was palpable over the greater trochanter and along the posterior margin of the trochanter there was great tenderness. The motions of the hip were free. Urinalysis and the Wassermann reaction of the blood were negative. Results of the blood count were within normal limits. Roentgenograms of the femur and thorax were also negative. The bursa was excised, at operation, there was found an enlarged and thickened cyst which contained two loose, fatty bodies. Convalescence was uneventful, on inquiry six months later, the patient reported that she was well.

In cases of inflammation of the bursa that lies over the greater trochanter, the patients

patellar ligament; when enlarged, it may present a swelling on either side of the patella. The suprapatellar bursa or pouch is, in my opinion, part of the knee joint. In the differential diagnosis of synovitis and bursitis, it is well to remember that in the former there is imparted to the palpating hand a ballottement or sensation of something floating when the patella is pushed against the femur; in the latter, the patella remains firmly against the bone. Popliteal bursae may result from outpouching of the synovial membrane of the knee joint, and when excision is attempted, the hernia will be found to come from the posterior cap-

sule (Figs 70 and 71) These and the bursae about the semimembranosus and gastrocnemius muscles are painful only when they cause pressure on the blood vessels and nerves The treatment is along the same lines as for other painful bursae unless a hernia of the synovial membrane is found, in which case an attempt should be made to close the opening by scarifying the capsule and suturing fibrous tissue over the

Fig 72—Location of bursae with relation to the muscles of the popliteal space

hole The patellar bursa which is not connected with the knee joint, is readily removed through a transverse incision with excellent results It is the common site of syphilitic bursitis and if a sinus persists, it is well to investigate for syphilitic infection Following extension a splint should be used to immobilize the knee for ten days

Case 10 A farmer aged seventy-eight, complained of a growth on the knee which had been present for twenty five years Four days previous it had ruptured

and drained He could not remember any definite trauma nor had he suffered any marked pain or discomfort The action of the knee was unimpaired

Examination disclosed a huge cystic mass prepatellar in origin which completely surrounded and obscured the patella There was an area of recent hemorrhage at the point of drainage which had healed and closed The systolic blood pressure was 230 mm of mercury and the diastolic 115 The pulse rate and temperature were normal Urinalysis was negative The results of the blood count were within normal limits Roentgenograms were negative except for evidence of a mass of soft tissue about the patella and evidence of calcified arteries A diagnosis of essential hypertension arteriosclerosis and prepatellar hygroma was made Under local anesthesia the mass was excised The pathologist reported that the tissue was a degenerating mucinous hemorrhagic cyst

Case 10 illustrates the fact that chronic bursitis may exist for many years without causing disability Figure 72 illustrates the appearance of the knee in a case which is not reported here

Case 11 A salesman aged forty nine complained of persistent pain and swelling about the right knee following a fall about nine months previous to admission and a second fall six months later Following the first injury, the pain had ceased in a few days but the swelling had persisted After the second injury the pain had persisted and had been aggravated by walking the swelling had enlarged

General examination did not disclose any foci of infection The results of a blood count were within normal limits Urinalysis and the Wassermann reaction of the blood were negative At operation an enlarged infrapatellar bursa was found which was filled with red jelly like material Several small collections of similar material were excised along the inferior border of the capsule and as far as the anserine bursa which was enlarged and contained a white jelly like material which was also excised Further examination disclosed an enlarged prepatellar bursa undergoing degenerative changes this was also excised The discoloration in the infrapatellar bursa was caused by blood the thick glairy mucinous jelly like material which was found in the anserine bursa was similar to that usually found in these cystic cavities The patient had an uneventful convalescence The pathologist reported 'three bursae' (Fig 71)

BURSAE OF THE FOOT

Bunion.—A bunion is an inflammation of the adventitious bursa over the head of the first metatarsal bone It may lead to formation of a sinus and extreme pain and may require excision The bony enlargement of the head of the first metatarsal bone may require removal, as hallux valgus is a common contributing factor Women's shoes especially the type with high heels are the

cause of such conditions in many instances, and proper footwear, with lower and broader heels as well as more roomy toe space, is essential for relief.

Bursae of the heel cause considerable discomfort, especially to women who wear poorly fitted shoes. These bursae become enlarged and painful, and are often infected. Removal of the cause of irritation is the best way of relieving the pain. The hard

inflammation has subsided. Later, the infected bursa may be removed or drained with safety. Because of modern footwear, the subcutaneous bursa which lies over the insertion of the tendo achillis is often involved, as is also an adventitious bursa over the head of the first metatarsal bone. The proximity of nerves in such regions makes the inflammation very painful, and recourse to pads and ointments is common; but the

Fig. 73.—The surgical technique employed. The oblique incision is made over the popliteal space and along the course of the cyst, the cyst is dissected free and the pedicle exposed at the point of entrance into the joint, cyst opened to show inner surface and hernial opening into the joint, and pedicle exposed after excision of cyst.

counter of the shoes may be removed in cases of inflammation of the bursa of the tendo achillis. A patient should stay off her feet if possible, especially when there is evidence of infection. I never incise for an acute bursal infection, because I feel that the association of bursae and the lymphatic structures may result in septicemia. In such cases, boric acid and alcohol dressings should be applied; after which the patient should be advised to remain in bed until the in-

quickest way to give relief is to have the patient wear proper footwear and rest the feet.

Case 12. A woman, aged twenty-one, came for relief of painful heels. Three years previous to admission, without illness or injury, aching pains had developed in the backs of both heels. Pain had persisted in spite of wearing pads, and the greatest relief had come with rest and walking on the toes.

Examination showed a thickened callous, with fissures over the posterior aspects of both calcanei and local tenderness. Roentgenograms of the feet were

negative. The patient was provided with proper shoes and pads.

Some styles of shoes with very high heels have been reduced in bulk until they are slippers which are difficult to hold on the feet. In order to make them secure, the counter has been drawn in so that it frequently cuts into the tendo achillis in the region of the subcutaneous bursa, the resulting trauma produces a callosity and bursitis. These bursae and callosities disappear with the use of properly fitting shoes and temporary pads. The danger that the fissures may become infected is to be emphasized as this infection may lead to lymphangitis and septicemia with fatal termination.

A common form of bursitis in the foot is that which develops under the tuber calcanei and the fatty pad over the heel. The inflamed bursa becomes exquisitely tender and makes walking and standing difficult. This bursa is often affected in infectious diseases and the condition may fail to be relieved by rest, heat or pads worn in the shoes, it then becomes necessary to excise the bursa through a lateral incision.

X THE VASCULAR SYSTEM

CONGENITAL ABNORMALITIES

According to the embryological studies of Sabin and Woodard arteries and veins develop from a common capillary plexus. At certain stages in this development vessels may serve interchangeably as carriers of arterial and venous blood before their final differentiation into arteries and veins. Moreover in embryonic life multitudinous direct communications between the arterial and venous systems have been observed without the interposition of a capillary bed. On rare occasions one or more of these direct connections may persist beyond uterine life.

Such abnormal communications are postulated as the primary factor in the development of hemangioma (nevus telangiectasis *mother's mark*), cirroid aneurysm (plexiform angioma racemose angioma) and congenital arteriovenous fistula. To similar variations in the development of arteries and veins from a common capillary plexus is ascribed the occurrence of port wine or claret stains which are pink or bluish discolorations of the skin due to numerous dilated intradermal vessels.

Angioma—An angioma (Fig 74) composed largely of dilated blood vessels and endothelium lined blood spaces in a framework of fibrous tissue and fat may arise in any part of the body including skin, subcutaneous tissue, muscles, long bones, vertebrae, skull, liver, brain or spinal cord. Although it is not strictly a tumor in the sense of a neoplastic growth, the dilated and elongated blood vessels with their contained blood produce a space-occupying mass which provokes symptoms characteristic of its location and size. Situated in a vertebra it may produce paralysis and anesthesia comparable to that resulting from a tumor of the spinal cord.

In the newborn an angioma may be present as a subcutaneous or deeply seated swelling easily compressible, sometimes pulsating and frequently appearing in the surface over a limited area as a mottled reddish or bluish mass over which the skin is

very thin. This swelling may spontaneously disappear presumably as a result of thrombosis of the abnormal communication or communications; it may remain stationary or it may grow rapidly depending on the size of the vessels abnormally connected and on the size of the abnormal communication itself. It may develop into a cirroid angioma, the large endothelium lined spaces of which may ulcerate producing serious or fatal hemorrhage. Occasionally the increased local heat, the red discoloration and thinned out appearance of the skin overlying a hemangioma may suggest the diagnosis of an abscess, a mortifying may take. An accurate and chronologic history should prevent such an error.

"Cirroid aneurysm" is properly only a descriptive term applied to a remarkable dilatation of vessels, arteries as well as veins, that occurs in the scalp, in the brain and in the subcutaneous tissues of the extremities, in connection with arteriovenous communications usually congenital in origin. However the frequent occurrence of a cirroid aneurysm about the scalp and head and its rapid postnatal development have suggested that the trauma of birth may by contusion be responsible for the abnormal opening between the artery and its adjacent vein. Cirroid aneurysms have been known to occur at the site of a hematoma caused during labor (Reid).

Congenital Arteriovenous Communications—The most frequent location of a congenital fistula is in the neck and in the extremities. Except in certain extremely unusual and remarkable instances the exact point of fistulous communication may be difficult to demonstrate as it may be impossible to say where the artery ends and the vein begins. Recorded in the literature are examples of such communications between the carotid and jugular vessels, the subclavian vessel, the tibial vessel, the brachial vessel and the intracranial vessels. The ultimate effect of such abnormal communications is to transfer blood under ar-

terial pressure directly into the venous bed, with resulting venous dilatation. When these communications are located in the extremity, engorgement and dilatation of superficial veins may be extreme and may be accompanied by ulceration of the skin. Operations for the relief of supposed varicose

the period of growth, particularly at the epiphysal line, brought about by the increased vascularity of the extremity. The decreased resistance to the flow of blood from artery to vein at the site of the fistula as compared to the resistance in the flow of blood through the capillary bed elsewhere attracts a large volume of blood to the fistula, thereby causing an opening up and dilatation of all vessels approaching the fistula. The surface temperature of the extremity may be increased, particularly in the neighborhood of the fistula, which is also an expression of the increased vascularity of the part. Blood withdrawn from a surface vein may be found to contain a considerable admixture of oxygenated arterial blood (Brown). This fact provides an authoritative test for the presence of an arteriovenous fistula. As in experimental and traumatic fistulas the heart may be enlarged, and the main artery proximal to the opening may be dilated.

The characteristic thrill and bruit of a fistula may be absent, but when present they are most pronounced over the site of the fistula and are propagated both distally and proximally along the course of the involved vein. Pressure directly over the opening obliterates the thrill and bruit, but pressure over the vein at any point proximal to the opening controls the bruit also, a fact which may lead to a mistake in locating the exact site of the abnormal opening. The intracranial fistula produces a bruit which can be heard both subjectively and objectively.

Treatment.—The treatment of *hemangioma* consists in excision as promptly as possible after birth to avoid further growth and extension. In certain cases, because of size, the excision is performed in multiple stages. Where large areas of skin are involved grafting may be necessary. About the face and head it may be found desirable to apply electric coagulation to small areas at repeated sittings.

Aneurysm is cured by excising or eliminating by ligation the abnormal opening or openings. This may be exceedingly difficult and may necessitate the removal of large masses of dilated vessels in order to be sure to include the abnormal openings, the exact site of which may not always be ascertainable. When the communications lie in

Fig 74—Congenital hemangioma of the hand. Note the marked dilatation of the superficial vessels, the dilated radial artery, and the increased length of the right radius and ulna.

veins have been performed with almost disastrous results because of arterial bleeding from veins. The affected extremity may be larger in circumference and its bones longer than those of its normal fellow (Fig. 74). The increase in the length of bone is ascribed to the improved nutrition during

the bone as in the extremities amputation provides the only cure. A hemangioma of the body of the vertebra has been known to respond favorably to radiation therapy. The use of a sterilized stethoscope at operation may prevent failure to obliterate all abnormal openings. As long as a bruit is heard the heart of the trouble has not been eliminated. Loss of blood must be avoided since a fall in blood pressure will in itself abolish the thrill and bruit and thereby prevent the detection of the site of communication. Failure to control all abnormal openings will result in a recurrence of dilated vessels—a circumstance which has led writers to consider a cirroid aneurysm as neoplastic in origin.

VASCULAR TISSUE TUMORS

Blood vessels are composed of an inner endothelial lining a fibroelastic supportive framework contractile tissue¹ which is smooth muscle in the larger vessels and pericytes¹ in the capillaries and a rich plexus of sympathetic nerves. Both benign and malignant tumors composed of these various elements are recognized. All are compounded of several tissues but each tumor type is characterized by some special feature from which its name is derived. They may develop at any age and wherever blood vessels are found but the great majority appear in the superficial tissues early in life and are often multiple. Most of them probably come from segregated vascular anlagen² which develop later than and separate from the vascular system although the tumor vessels usually contain circulating blood. The simplest tumor form is the *capillary hemangioma*. If the capillaries are widely dilated into spaces the tumor is called *cavernous hemangioma*. If the component vessels have smooth muscle in their walls the term *venous hemangioma* is applied. Fat and extravascular smooth muscle

are sometimes associated. If the stromal smooth muscle predominates the growth is a *vascular leiomyoma*. Skin leiomyomas³ may cause attacks of paroxysmal pain. The vascular tumors characterized by a dominance of endothelial cells are called *hemangioendotheliomas*⁴. Most of these tumors are malignant but a rare benign form occurs in infants. The vascular tumors in which pericytes predominate are called *hemangiopericytomas*. The best known variety of these last is the *glomus tumor*^{5, 7} so called because it is an hypertrophied caricature of the specialized arteriovenous anastomoses found in the hands and feet which are concerned with temperature control.⁸ The glomus tumor may occur anywhere in the skin or beneath it but is commonest in the hands especially beneath the nail. In spite of its small size it frequently occasions paroxysmal attacks of agonizing pain. Only excision will cure the pain. Other superficial tumors occasionally cause paroxysmal pain⁹ but it is commonest with glomus tumors and leiomyomas.

Rarely the *hemangiopericytoma* may display aggressive growth and metastasize⁶ but the more familiar malignant tumor is the *hemangioendothelioma*. Although maintaining a basic tendency to form vascular tubes the malignant endothelial cells heap up within the lumens and sometimes dominate the whole field.⁴ Metastases occur freely through the blood stream. The majority of the malignant hemangioendotheliomas are found in the liver spleen and superficial soft parts but they can arise in many other organs and tissues. The validity of the claim that malignant fibrous and smooth muscle tumors arise from the walls of large blood vessels is in question^{10, 11}. Another possible example of malignant vascular tumor is furnished by Kaposi's disease¹ but it is questionable whether or not the disease is neoplastic.

The clinical aspect and treatment of these tumors vary so greatly that it would be confusing to attempt any dogmatic summary statements about them.¹² Almost all of them grow by infiltration at rates of speed extremely variable even for the same tumor at different times. All of the malignant tumors and many of the benign ones are best treated by excision but some benign ones are better dealt with by radiotherapy. In

injections of sclerosing fluids or boiling water or by some combination of methods.

WOUNDS

Hemorrhage from a wounded artery may be external and easily controlled by digital pressure, or it may be concealed and rapidly fatal, as into the soft tissues of the thigh following fracture or into the capacious thorax following a puncture wound of the inaccessible innominate artery or into the abdomen following a stab wound of the iliac artery. Concealed hemorrhage should be suspected in a patient with a steadily rising pulse rate, an increasing respiratory rate, with air hunger, pallor, extreme restlessness, faintness and, finally, in rapid succession stupor, delirium, unconsciousness and death. Short longitudinal wounds of an artery are less dangerous than transverse wounds, and complete division of an artery may cause less bleeding than a tangential wound or partial division. When an artery is completely divided, the highly elastic quality of its wall causes it to retract into the tissues, thereby diminishing the caliber of the vessel and promoting clotting. Following incomplete division, the same elasticity causes the edges of the wound to gape even more widely, thus promoting bleeding.

The escape of blood into the soft tissues through an arterial wound may lead to the

development of a large pulsating hematoma which exhibits expansile pulsation and a to and fro bruit with a brief silent interval between the two phases. Beyond such an aneurysmal hematoma, pulsation in the arteries may be absent, the tissues may show a distinctly impaired circulation and gangrene may be imminent. If the wound in the artery is untreated the pulsating swelling may grow progressively larger, causing dis-

Fig. 75.—Traumatic arteriovenous fistula between femoral vessels due to a gunshot wound. The circle marks the entrance site of the bullet. Note the increased size of the affected extremity, the dilated superficial veins and the varicose ulcer below the knee. The common femoral artery on the left was greatly dilated as compared with that on the right.

coloration, thinning and finally destruction of the overlying skin with perhaps fatal hemorrhage. Progressive growth of a swelling also increases the danger of gangrene of the extremity due to interference with the collateral circulation secondary to pressure of the aneurysmal mass. The localized pain and tenderness, the increased local heat, the redness and infiltration of overlying tissues may be mistakenly interpreted as being due to infection rather than to an aneurysmal

hematoma, a mistake attributed to many masters of the past, even to the doughty Pott and the testy Dupuytren.

When a wound of the artery involves the vein as well, a traumatic *arteriovenous fistula* is the result (Fig. 75). The temporary profuse bleeding may be easy to control, since the blood from the arterial wound is shunted directly into the vein. The extremity beyond the wound may swell to great size as a result of edema of the tissues incident to arterial pressure in the venous bed. Gangrene may develop, requiring amputation of the extremity, or the patient may

the circulation of the blood. It provides two routes through which the circulating blood may pass. Blood may flow through the normal channels as represented by the system of heart-artery-capillary bed and vein, or it may traverse a shorter circuit consisting of the heart-artery-fistula and vein (Fig. 76). Because of the fistula the peripheral resistance in the shorter circuit is considerably less than the resistance in the normal circuit.

Obviously the extent of the reduction in peripheral resistance and the amount of blood diverted through the fistula will depend on the size of the opening. A small

Fig. 76—*a*, Diagrammatic representation of the circulation in the presence of a femoral fistula, *b* ligation of the artery alone proximal to the fistula inevitably invites gangrene because of diversion of the collateral circulation through the fistula back to the heart, *c*, ligation of the artery and vein may prevent gangrene but does not cure the fistula.

die promptly from cerebral and myocardial anemia because of loss of blood and diversion of what little blood remained on the arterial side through the fistulous opening into the venous bed. The characteristic thrill and bruit are invariably present although sometimes delayed in appearance for days because of shock and low blood pressure. These are continuous through the cardiac cycle and not interrupted or biphasic as in a simple aneurysm. They are markedly accentuated during systole and are best felt and heard over the site of the fistula.

A fistula, if large, introduces profound disturbance in the physiologic laws governing

communication, not over 3 or 4 mm. in diameter, may exist between peripheral vessels for years, and aside from the mild local disturbance due to the continuous thrill and bruit, no other effects develop. The larger sized fistulas, from 5 to 15 mm. in diameter, divert so large a volume of blood from the general circulation that startling effects on the circulatory mechanism are produced. The immediate effect is a fall in general blood pressure and a marked acceleration in pulse rate. Within a few days a gradual readjustment begins which ultimately leads to complete recovery of the systolic blood pressure, and a gradual return to a normal pulse

rate. The primary factor in this recovery is an increase in the total blood volume an increase which has been shown experimentally to be commensurate with the size of the fistula.

If the fistula is large closure by digital compression by operation or by closure of the artery proximal to the fistula produces an abrupt rise in blood pressure and a fall in pulse rate (Fig. 77). Reopening of the fistula causes a fall in blood pressure and a reacceleration in pulse rate. These phenomena when present are pathognomonic of an arteriovenous fistula as they do not occur

in the presence of other aneurysmal dilatations of the arterial bed—would lead to an excessively high blood pressure were it not for another compensatory mechanism. By overdistention of the arch of the aorta the depressor fibers of the vagus are stimulated the pulse rate drops the cardiac output is reduced and the excessive increase in blood pressure is prevented.

Another striking though not invariable feature of an arteriovenous fistula is the accompanying dilatation of the heart. This dilatation is progressive and may eventually result in cardiac decompensation and death.

Fig. 77.—Chart illustrating the remarkable rise in blood pressure and fall in pulse rate when a femoral fistula is closed by digital compression and the fall in pressure and rise in pulse rate when the fistula is open. Features absolutely pathognomonic of an arteriovenous aneurysm as compared to a simple aneurysm.

in the presence of other aneurysmal dilatations.

The increase in general blood pressure when a fistula is closed depends on two factors normally intimately concerned with the maintenance of blood pressure: (a) the elimination of the fistula forces the circulating blood to pass through the normal capillary bed thus increasing peripheral resistance; (b) closure of the fistula forces the volume of blood formerly diverted through the fistula and for which compensation has occurred by an increase in total blood volume into the general arterial bed. The two circumstances—an increase in peripheral re-

sistance and an increased distention of the arterial bed—would lead to an excessively high blood pressure were it not for another compensatory mechanism. By overdistention of the arch of the aorta the depressor fibers of the vagus are stimulated the pulse rate drops the cardiac output is reduced and the excessive increase in blood pressure is prevented.

The dilatation also involves the artery leading to the fistula and the veins lying both proximal and distal to it. Elimination of the fistula by operation causes a temporary overdistention of the already dilated heart followed by a gradual subsidence of the dilatation. The dilatation which is limited to that part of the circulatory system through which the short-circuited blood passes is ascribed to the distending force of the greatly increased blood mass flowing through these vessels and the heart by way of the fistula. The volume of blood flowing through the heart is practically doubled following the introduction of a fistula.

Treatment—Temporary control of the hemorrhage in the period between injury and operation is effected by direct pressure on the bleeding point preferably with sterile gauze by digital pressure on the artery above the injury or by the application of a tourniquet when feasible. The latter should be avoided unless prompt operation can be undertaken since prolonged ischemia below a tourniquet favors (a) permanent nerve paralysis (b) gangrene due to interference with collateral circulation and (c) infection in tissues damaged by a lack of nutrition. Ligation of vessels in the presence of infection invites the danger of secondary hemorrhage due to destruction of the vessel wall and of the obliterating thrombus by microorganisms.

When feasible wounds of large arteries should be sutured promptly after their in-

jury under a tourniquet and the wound in the artery sutured or if this is impossible the artery should be ligated above and below the wound with complete division of the artery if it is not already so divided. If a tourniquet cannot be applied the artery above and below the laceration should be exposed through separate incisions if necessary and encircling tapes should be applied but not tied to be drawn tight for control of hemorrhage in case of need. By including in this temporary ligature a short segment of rubber tubing of the same diameter as the artery injury to the arterial wall is prevented and removal of the ligature is easily effected by cutting down on the tubing (Gordon Taylor).

In operating upon a pulsating hematoma or upon an arterial lesion with failure of the upper thigh where a tourniquet is not

Fig. 8—A divided artery is most easily resutured according to Carrel's method of converting the circular artery into a triangular one by the application of three transverse sutures.

sufficient before inflammation has set in (Fig. 78). This depends on being able to control the hemorrhage from the wound by the application of a tourniquet above it or of small rubber shod clamps to the artery proximal and distal to the wound. Use silk threaded on very fine needles and moistened in sterile white oil is the suture material used for arterial wounds. When available heparin should be administered for forty-eight hours after suture.

Occasionally in wounds involving tissues contiguous to a large artery the artery may be affected by a localized spasm sufficient to compromise the circulation beyond. Periarterial sympathectomy above and at the site of the spasm may be effective but if not interruption of the sympathetic trunk governing the vessel lumbar or thoracic is indicated.

A pulsating hematoma should be evacu-

ated under a tourniquet and the wound in the artery sutured or if this is impossible the artery should be ligated above and below the wound with complete division of the artery if it is not already so divided. If a tourniquet cannot be applied the artery above and below the laceration should be exposed through separate incisions if necessary and encircling tapes should be applied but not tied to be drawn tight for control of hemorrhage in case of need. By including in this temporary ligature a short segment of rubber tubing of the same diameter as the artery injury to the arterial wall is prevented and removal of the ligature is easily effected by cutting down on the tubing (Gordon Taylor).

Because of its progressive effects on the heart and circulation an arteriovenous fistula should be eliminated. If seen immediately after infliction the arterial and venous wounds may be sutured with restoration of the vessels. If the fistula is of recent origin delay in operating may be counselled (1) because small fistulas tend to heal spontaneously and (2) because delay favors the development of a collateral circulation and

diminishes the danger of gangrene if ligation of the vessels is found necessary. Whenever dilatation of the heart has occurred and alterations in pulse rate and blood pressure occur on digital closure of the fistula one may be certain that spontaneous closure is unlikely and that operation is necessary.

If it is a fistula of some duration the vessels may be separated and the wounds sutured or the rent in the artery may be sutured through an incision in the vein which is then ligated (Matas). Under no circumstances should the artery proximal to a fistula be ligated as for a simple aneurysm (Fig 76). Because of the absence of peripheral resistance at the fistula blood flowing through the collateral vessels would find its way through the fistula back to the heart instead of into the tissues distal to the fistula and gangrene would inevitably occur. The safest treatment consists in ligation of all vessels leading to and from the fistula followed by actual excision of the fistula.

Prolonged rest and a slow return to work are indicated after such excision. Considerable myocardial weakness may have developed during the prolonged period of dilatation and the cardiac muscle may prove temporarily inadequate against the increased peripheral resistance and the rise in diastolic pressure which follow the closure of a fistula.

Pulsating Exophthalmos—Fractures of the skull involving the sphenoid bone are occasionally accompanied by partial rupture of the carotid artery where it lies within the cavernous sinus. This is a variety of arteriovenous fistula which produces its own unique symptoms: a gradually protruding eyeball which finally becomes fixed, marked congestion and edema of the conjunctiva and numbness of the face and ptosis of greater or less degree. Subjectively such a lesion produces an intolerably noisy intracranial bruit from which the patient can never escape and which he feels will drive him insane if it cannot be controlled.

Immediate treatment consists of complete rest in bed, limitation of fluids and no straining or effort, not even at stool. Pressure over the common carotid artery, applied three daily, promotes closure by thrombosis at the site of communication.

Operative treatment consists in ligation of the internal carotid artery either through a transverse incision in the neck or intracranially as advocated by Dandy. The danger of hemiplegia due to cerebral ischemia prompts certain precautions. Simultaneous ligation of the jugular vein is considered mandatory by Watkins and others. Keegan first ligates the common carotid artery thus providing collateral circulation through the external carotid artery followed subsequently by ligation of the internal carotid artery if all symptoms do not disappear. These ligations may be performed with the patient under local anesthesia and the ligature may be removed if evidences of cerebral ischemia appear, i.e. somnolence, unconsciousness or hemiplegia, numbness and convulsions on the side of the body opposite the ligation.

Ligation of Arteries—In the ligation of large vessels the application of a ligature sufficiently tight to close the lumen invariably causes death of the tissue included in the ligature (Halsted). Healing occurs by envelopment of the ligature in fibroblasts and the substitution of fibrous tissue for the devitalized wall within the ligature. If a fine ligature is applied to a vessel in continuity the repeated trauma of expansile pulsation against a fixed point may result in rupture of the devitalized vessel wall at the point of ligation. A heavier ligature reduces the possibility of erosion of the vessel wall. Accordingly, one may to advantage graduate the size of the ligature in proportion to the size of the vessel to be ligated (Reid). In ligating the abdominal aorta for example one would apply a tape ligature or a strip of fascia lata about $\frac{1}{4}$ inch in width. The best protection against fatal erosion is ligation of the vessel at two points and division of the vessel between the ligatures. Following division retraction of the divided ends occurs and the force of each pulsation is no longer concentrated on a fixed point but is dissipated with each pulsation over a wider area through elongation and expansion of this thickened retracted end. Moreover ligation in continuity is frequently followed by re-establishment of the lumen nullifying the desired effects of such ligation.

In ligating large arteries one must always

consider also the necessity of maintaining a proper balance between the arterial and venous systems by simultaneously ligating the vein as well as the artery. Statistically Sehrst and Heidebreich have demonstrated the lessened incidence of gangrene following ligation of artery and vein as compared to the ligation of the artery alone a fact corroborated experimentally by Brooks. If division of the artery is followed by pulsation in the distal stump the vein need not be ligated since there is already an abundant collateral circulation (Pemberton). If the division of the artery is not followed by pulsation in the distal stump the vein also should be ligated in the hope of improving circulation beyond the divided artery by an increased resistance to the return flow to the heart of the collateral circulation.

Before the ligation of major peripheral arteries blocking the lumbar sympathetics in the case of the lower extremity and the cervicodorsal sympathetics in the case of the upper extremity has been advocated as a means of increasing the collateral circulation. The vasodilatation that accompanies such blocking may be sufficient to prevent gangrene. The blocking is effected by the injection of novocain followed by 3 to 5 cc of 95 per cent alcohol (Gage and Ochsner).

With reference to the carotid vessels one may ligate the internal carotid or common carotid in children and young adults with impunity but in old adults ligation of the carotid should invariably be accompanied by ligation of the jugular vein also.

OCCLUSIVE DISEASES OF THE PERIPHERAL VESSELS

I RAYNAUD'S DISEASE

(See section on Raynaud's Disease)

II THROMBOANGITIS OBLITERANS

(*Endarteritis Obliterans* of Hünimayer (1879). *Pseudo Juvenile* or *Spontaneous Gangrene* *Buerger's Disease*)

Thromboangitis obliterans is an occlusive disease of both arteries and veins occurring most conspicuously in either upper or lower extremities where it may be responsible for the maddening pain of ischemic stubborn infections or gangrene. The same occlusive process has been described as occurring in the vessels of the brain, the heart, the kidney and the intestines. Although slowly and insidiously progressive and usually culminating in gangrene or death it is characterized by remarkable chronicity with prolonged remissions and occasional apparently permanent recoveries. Its frequent occurrence in young male adults given to excessive smoking and its extreme rarity in females early suggested tobacco as an etiologic agent. Additional evidence, however, absolves tobacco as the primary cause of the disease but as an excitant of the sympathetic nervous system tobacco may cause contraction of blood vessels already partially occluded and thereby aggravate the deleterious effects of such partial occlusion (Coller). Smoking by patients with thromboangitis generally results in decreased peripheral cutaneous temperatures, an increased pulse rate, an elevated blood pressure and a decreased oxygen saturation of the arterial blood (Theis-Freeland). Originally thought to be limited to the Jewish race, thromboangitis has since been de-

scribed in Gentiles, Orientals and Turks. Although tobacco, the ingestion of ergot and some obscure infectious agent have been invoked as probable causes of the disease, no definite etiologic agent is known at present. Epidermophytosis is said to have an etiologic significance (Thompson).

Pathologically, both the large and small vessels of a limb—veins as well as arteries—may show various stages of cellular thickening and proliferation of the intima associated ultimately with thrombosis limited to certain portions of the vascular tree.

Fig. 79.—Injection of the arterial tree in an amputated extremity in a case of thromboangiitis obliterans illustrating the remarkable level of collateral vessels. Compare with Fig. 81 (Reichert).

Subsequently this clot becomes organized, new vessels permeate the occluding mass of fibrous tissue and the lumen is partially restored. In the lower extremity the obliterative process may extend as high as the popliteal and femoral vessels but unlike arteriosclerosis it does not extend uniformly throughout the peripheral vascular bed. In the larger vessels occlusion alternates with patency and one may find in a given vessel all stages of thrombosis from a fresh soft clot to a completely organized recanalized thrombus.

As the disease advances there develops also an extensive perivascular fibrosis involving vein, artery and nerve, all of which may become matted together in a fibrous cord. It is probable that this involvement of the nerve in a chronic fibroblastic inflammatory process accounts for the excruciating pains to which victims of this disease are occasionally subject. Proceeding *pari passu* with the occlusion of the larger vessels by intimal proliferation and thrombosis there develops a collateral circulation (Fig. 79) which for varying periods of time provides an adequate circulation for the ordinary nutrition of the part below the occlusion and undoubtedly helps to explain the great chronicity of the disease and the delay in the development of gangrene.

Symptoms and Signs.—The subjective and objective symptoms of thromboangiitis obliterans are those common to nutritional ischemia of whatever origin. Subjectively, the most frequent symptom is pain varying from slight discomfort in a foot or leg—at times mistakenly attributed to flatfoot, varicose veins or arthritis—to an intolerable demoralizing pain for which only amputation provides relief. In some patients comparative ease is secured only by complete rest and the slightest exertion produces painful and incapacitating cramp, sometimes located in the toes, ankle, calf and even thigh. This sequence of painful limping accompanying exercise with relief from pain when at rest is known as *intermittent claudication* and is probably related to the greater production, incomplete removal and therefore increased accumulation of lactic acid in anoxic and ill nourished tissues.

In other patients fair comfort is experienced during a day of limited exertion but at night is approached with dread because of the terrors of so-called 'rest' pain relieved at times only by lying with the affected leg hung over the side of the bed. Its absence during moderate exercise is ascribed to the assistance to circulation which comes from muscular compression of the larger veins.

Other painful sensations of thromboangiitis are described as a soreness, an aching in the muscles, a persistent and increasing burning, a numbness or just coldness of

the toes, foot or lower leg. Early and excessive fatigability of the affected extremity may be an early symptom.

The objective signs are no less characteristic and if properly sought for and observed should prevent such erroneous diagnoses as fallen arches, rheumatism and subcutaneous infections. Early in the course of the disease there appears the phenomenon of erythemic pallor on elevation of a limb above the cardiac level and deep redness or cyanosis on standing erect. When associated with absent pulsation in the posterior tibial and dorsalis pedis arteries this phenomenon of pallor and rubor depending on position is diagnostic of an occlusive vascular disease and the degree of such pallor and rubor roughly indicates the degree of vascular occlusion. So closely do the redness

large calloused areas and small areas of dry gangrene (Fig 80). Small nodosities along the line of the superficial veins probably represent involvement of the valves in the course of the veins. Vasomotor phenomena such as sudden pallor in one or more digits accompanied by numbness or dull discomfort may occur following exposure to cold and may disappear entirely following massage and heat. Edema occurs in the late stages of the chronic type of disease and occasionally early in the acute type in which gangrene is an early development requiring amputation. Amputation through an edematous area is absolutely contraindicated as it results in a non-healing stump and reamputation is invariably necessary.

COMMANDER EMIL HOLMAN

Fig 80—Trophic changes of the nails and circumscribed gangrene of the fingertips in a case of thromboangiitis obliterans involving both upper and lower extremities.

and pain suggest infection that the diagnosis of a deep-seated abscess is sometimes erroneously made for which an ill-advised operation is performed and from which non-healing wounds result. Similarly slight injuries such as blisters from shoes or cuts from paring the nail and accidental abrasions result in non-healing wounds. Such breaks in the protection afforded by the skin permit the entrance of pyogenic organisms into poorly vascularized and therefore poorly nourished areas resulting in great accentuation of all symptoms, particularly pain. Non-healing infected wounds are frequently the precursors of gangrene.

Phlebitis of the superficial veins is considered by Buerger as one of the characteristic features of this disease. Other so-called trophic lesions may develop such as shallow indolent ulcers, hypertrophied toe nails

III. ARTERIOSCLEROSIS

Arteriosclerosis is an important cause of circulatory disturbances in advancing age due to a slowly progressive narrowing and obstruction of the peripheral vessels largely through a proliferative overgrowth of the intima and degenerative changes characterized by the deposition of fatty and atheromatous material in the arterial wall. Scar tissue and calcareous deposits replace the fatty deposits and the vessel loses its normal elasticity. The formerly plastic vessel becomes progressively more rigid and more contracted, increasing stagnation of the blood stream follows and varying degrees of thrombosis occur to increase the narrowing of the circulatory bed.

These changes are very slowly though inevitably progressive and unlike thromboangiitis obliterans take place more nu-

formly throughout the peripheral bed (Fig 81). The collateral circulation is minimal and remissions rarely occur.

The usual symptoms of ischemia are present: paresthesias and numbness of the digits, sensitiveness to cold, intermittent claudication appearing after shorter and shorter periods of exercise, intolerable pains while at rest, non-healing fissures and wound, stubborn infections, the trophic changes of dry skin, calluses and hypertrophied nails, pallor on elevation, rubor in the dependent position and absent pulsation in vessels all make their appearance in greater or less degree over a period of months—sometimes years. During the period of progressive ar-

teriosclerosis has been ascribed to anemia of the spinal cord. Experimental confirmation of this explanation has been developed by Reichert, who was able to produce the same evidence of weakness and intermittent claudication in the legs of dogs by ligation of the abdominal aorta or of the lumbar segmental arteries that supply the lower portion of the spinal cord. Reichert was also able to produce unilateral claudication by unilateral occlusion of the lumbar segmental arteries. This syndrome should be borne in mind in elderly persons with marked arteriosclerosis and a history of intermittent claudication in the thighs but without marked evidence of peripheral vascular occlusion.

Fig 81—Injection of the arteries (a) of the normal vascular bed and (b) in arteriosclerosis showing the closure of the large vessels and the absence of a collateral bed. Compare with Fig 79 (Reichert).

terial occlusion the patient may secure comfort only by progressively restricting his activities within the limits of his circulation.

An occasional arterio-sclerotic patient is encountered whose complaint of weakness in the thighs coming on after walking a short distance accompanied by cramps limited to the thighs or a feeling of tightness in the muscles of the legs suggests peripheral vascular occlusion. Examination of the vessels, however, shows pulsation to be present though in diminished degree associated with definite neurological disturbances such as hyperreflexic reflexes and difficulties with sphincter control. Roentgenograms of the pelvis will reveal marked arteriosclerosis of the abdominal aorta. The symptoms have

Diabetic Arteriosclerosis—The underlying pathologic changes occurring in gangrene complicating diabetes are (1) a more or less advanced arteriosclerosis and (2) thrombosis in already diseased vessels by the introduction of infection through abrasions or minor wounds of the skin. Hence the extraordinary care that must be devoted to the feet in the elderly diabetic patient, so as to avoid injury or chafing and thus prevent the entrance of organisms into tissues ill prepared to combat them. When gangrene occurs on an arteriosclerotic basis amputation must be done at a higher level than when the gangrenous process is largely due to infection. When good pulsations are present in the posterior tibial and dorsalis pedis

arteries gangrenous digits may be amputated locally in the hope that control of the diabetes by insulin will arrest the infection and permit healing. Adequate drainage of infected fascial spaces supplemented by control of the diabetes may completely arrest the process.

COMMANDER EATLE HOLMAN

IV SYPHILITIC ENDARTERITIS

Occasionally widespread changes which are directly attributable to syphilis occur in the arterial wall of comparatively young persons. Marked round cell infiltration of the media, fragmentation and destruction of the elastic lamellae, overgrowth of the intima and finally secondary thrombosis are noted. All changes which eventually obstruct the lumen of vessels and produce the characteristic signs and symptoms of vascular deficiency. In addition to the usual treatment of peripheral vascular occlusion which will be outlined presently, treatment of the causative factor, syphilis, is in order.

V VASOSPASM COMPLICATING ARTERIAL OCCLUSION

An important feature of peripheral vascular disease, particularly thromboangitis which has led to profound modification of its treatment in the past few years is that in many instances diminished circulation is due as much to functional occlusion by vasoconstriction as it is to organic changes in the arteries. This vasospasm apparently involves not only the partially occluded vessels but also the collateral vessels. It is considered to be a reflex response to various impulses having their origin in the inflammatory process involving the arteries and the accompanying nerves. Vasomotor phenomena such as sudden pallor in one or more digits, numbness and dull discomfort may occur after exposure to cold and may disappear entirely after massage and heat treatment. The close resemblance to the vasomotor disturbances of Raynaud's disease has made it difficult at times to state whether a given condition should be classified as one of well advanced Raynaud's disorder with incipient gangrene or as a case of early thromboangitis which is in the pre-gangrenous stages.

Many tests have been devised to ascertain the degree of vasospasm complicating organic occlusion. Typhoid vaccine administered intravenously produces a chill and fever and generalized vasodilatation including the affected extremity. The temperature of the great toe is determined with a Tyco's dermaterm. It varies normally from 90° to 33° C. the oral temperature being 37° C. In vascular occlusion the temperature of the toe may be as low as 20° to 25° C. After the administration of typhoid vaccine the oral temperature may rise from 37° to 39° C. but owing to the vasodilatory effect of generalized fever the temperature of the toe may rise from 25° to 30° C. This indicates a marked degree of vasospasm.

Spinal anesthesia will release the vasoconstriction imposed by an overactive sympathetic system. Paravertebral block of the lumbar ganglia following injection of novocain will also interrupt the sympathetic nerves to the lower extremities as will also the blocking of peripheral nerves with novocain.

The simplest method available is that described by Landis. After the skin temperature of the great toe has been taken both arms are immersed for thirty-five minutes in an arm bath of water at a temperature of 43° to 45° C. Generalized vasodilatation is induced and the temperature of the toe is again taken after ten minutes. If the digital temperature rises above 32° C. organic occlusion of the blood vessels is definitely excluded. If the digital temperature fails to rise or rising fails to reach 32° C. the presence of organic obstruction is indicated. In the presence of other evidences of organic occlusion the degree of vasospasm is determined by the degree of rise in the temperature of the big toe which occurs following warming the hands.

TREATMENT OF PERIPHERAL VASCULAR OCCLUSION

Certain general precautions must be observed by every patient. Never again should he disregard the facts that his arteries are clogged, that his only hope of avoiding amputation lies in being able to develop a collateral circulation sufficient for ordinary needs and that he must be content to restrict his activity within the limits of the

available circulation. Chilling of even a limited part of the body is dangerous, cold or chilled hands or head will evoke vasoconstriction in the feet, just as vasodilatation of the hands produces vasodilatation of the feet. Each time such vasoconstriction occurs some permanent damage to tissues may result by precipitating an extension of the existing thrombosis. The patient is instructed to wear warm overshoes preferably fur lined and fur lined leggings in severely cold weather. Warm gloves to avoid chilled fingers and the proper protection of the head, ears and neck are stressed. Woolen socks and comfortably large shoes should be worn loosely laced over the dorsum of the foot.

At the first recognition of a vascular disorder attention should be directed toward meticulous care of the feet guarding them against trauma against injury while nails or corns are being pared and against the injury of ill advised minor surgical procedures such as the opening of a supposed abscess. The skin is washed daily, gently dried and rubbed with lanolin. Slight cuts or abrasions are washed with soap and water dried and covered with a small sterile dressing. The use of strong antiseptics such as iodine, lysol or cresol, is interdicated instead a 1 per cent aqueous solution of gentian violet is prescribed for some use. Any injury or abrasion however slight, should be under a physician's care until healed. An infected wound requires careful supervision and rest in bed until healed.

The patient with thromboangiitis has a diminished blood volume and an increased blood viscosity. Every effort should be made to increase the volume and diminish the viscosity by the ingestion of a large amount of water 3 or 4 quarts daily by actual measurement and daily charting. For the acutely ill patient requiring hospitalization Silbert finds great help by administering 300 cc of a 5 per cent solution of sodium chloride intravenously every other day for several weeks. Repetition of the course may be in order after an interval of one or two months.

The patient is taught by actual observation the optimum position in which the foot is neither too pallid because of too great elevation nor too cyanotic because of too great dependency (Reid). Superficial veins should be neither collapsed nor distended. When lying down the patient should attempt to approximate this optimum position and when sitting he should elevate his legs on a chair in front of him whether at home in his office or out riding.

Baerger's simple exercises should be performed two or three times a day: elevation of the foot for one minute, a horizontal position for three minutes and a dependent position over the edge of the bed for two minutes. When the leg is in a horizontal or dependent position the toes and ankle should be flexed thus aiding the return flow of blood by the muscular compression of veins. The patient is cautioned against standing in one position and when it is necessary to stand he

should move his toes and ankles constantly to assist the circulation.

Optimum nutrition is mandatory. The patient should be given explicit directions concerning a high vitamin diet containing plenty of fresh uncooked vegetables and fruits, butter and milk, haliver oil capsules, brewers yeast tablets and lemon juice are prescribed. If the patient has a low blood pressure the basal metabolism rate is determined, thyroid is administered if the rate is less than minus 5. Anemia is corrected by the necessary nutritional elements including liver and iron.

Tobacco in any form is absolutely prohibited. Experiments on normal subjects regarding the effects of smoking have shown a decrease in peripheral blood flow ranging from 57 to 83 per cent, with a corresponding drop in peripheral skin temperature, the average drop being 5.3° F and the maximum drop 15.5° F. A slowing and actual stoppage of blood flow in the capillaries of the nailfold have also been observed (Lampson, Wright and Moffat).

The patient is taught the value of producing twice daily a generalized vasodilatation by immersing the arms in water heated to 42° C or 108° F (Landis and Gibbon). The same vasodilatory effect may be obtained by the application of an electric heating pad over the abdomen for thirty to sixty minutes once or twice a day (Wright).

Additional measures depend on the complicating features of the vascular occlusion. The patient with threatened gangrene in toe or toes and with a painful open wound must be put to bed preferably in a hospital and kept there until the crisis is past or the wound has healed. As Reid suggests such a patient can well afford in order to save his limb and probably his life to spend six, eight or twelve months in an effort to restore his vascular equilibrium. Various measures are available before resort is made to radical treatment by amputation.

Intermittent venous hyperemia produced twice daily for thirty minutes by the alternate inflation and deflation of a blood pressure cuff applied to the thighs as described by Collens, Wilensky and de Takats, will have a beneficial effect. The pressure of the inflated cuff should not exceed the diastolic level, and the length of inflation should be determined by the appearance of definite rubor in the foot, usually within two or three minutes. The period of deflation should be double the period of inflation followed by one minute of elevation of the limb. The average cycle would then, be two minutes of compression, three minutes of release and one minute of elevation.

Intense pain may be controlled by crushing selected peripheral nerves exposed under local anesthesia. The posterior tibial nerve, the deep and superficial peroneal nerves and the sural nerves may be crushed singly or in combination. The exposure and crushing of nerves should never be done in the presence of lymphangitis nor near areas of phlebitis and should be done with a minimum of operative trauma (Smithwick and White).

In the presence of both arterial occlusion and large varicosities of the superficial saphenous system saphenous ligation and injection of the veins with 20 per cent salt solution may give beneficial results.

In a patient with marked vasospasm permanent interruption of the lumbar sympathetic chain may be effected either by operation or by injection with 95

per cent alcohol (Flathow and Reichert). The efficacy of such a procedure should first be determined by temporary interruption of the lumbar sympathetic nerves with novocain. The degree of comfort and increased range of walking obtained by such a temporary interruption are sometimes remarkable. The interruption may be made permanent by the injection of 1 or 2 cc of 0.5 per cent alcohol.

The injection of typhoid vaccine to produce vasodilatation is contraindicated in advanced arteriosclerosis because of the danger of thrombosis during the period of peripheral vasoconstriction that precedes the fever and dilatation (Allen). For a young adult with thromboangitis it is an excellent agent if performed with the patient in a hospital bed preceded by active vasodilatation through overheating. In the first dose 25-100,000 bacteria may be given increased by 50,000,000 with each dose until 300,000,000 are given at a time. Injections are given at intervals of four to seven days until 6 to 8 injections have been given. The course may be repeated in two or three months. The patient should be admitted to the hospital for at least a day for each injection.

The treatment of inadequate circulation in the extremities by alternate suction and compression as developed by Lindus Reid and Herrmann seems to have its greatest usefulness in acute arterial occlusion due to embolism. The improvement in appearance and comfort of an ischemic limb when placed in a special boot (the pavaex boot) designed to provide alternately negative and positive pressure is startling. Its efficacy in thromboangitis has not been clearly demonstrated although in the absence of open infected lesions or of netive thrombophlebitis it may provide some improvement. Its use is contraindicated in the presence of open infected areas as the massage of inflamed tissues causes unbearable pain and leads to a spread of the inflammation. Definite though often temporary improvement has been demonstrated after its use in arteriosclerotic ischemia. Caution is again indicated in the presence of open infected lesions.

Reasoning that the failure of the pavaex boot to improve embolism may be due to its inability to influence already obliterated channels a suction and pressure chamber was developed for application to the thigh where vessels are supposedly more easily influenced by external forces (Holman and Schulte). Within the cylinder pressures of +30 to +50 mm and -60 to -70 mm of mercury are alternately produced every five seconds. The cylinder can be applied to the thigh without harm or pain in the presence of open lesions on the toes or feet and has been found more effective than the pavaex boot in improving comfort and circulation.

ERYTHROMELALGIA

(Functional Hyperemia Weir Mitchell's Disease)

Erythromelalgia is a rare affection usually of the feet characterized by pain flushing and local heat made far worse if the parts hang down. It is attributed to excessive vasodilatation and is thought by some to be the opposite of Raynaud's disease. Full, bounding pulsation may be felt in the vessels of the affected foot. The skin is flushed and warm. Elevation and the application of cold are the known remedies. The condition warrants consideration only to call attention to the fact that peripheral vascular occlusion is also accompanied by a painful rubor, but the affected part is *cold not warm* both objectively and subjectively. On the theory that it is a disturbance in the sympathetic control of the blood vessels Reichert has abolished their control by alcoholic injection of the lumbar sympathetic ganglia with definite improvement in comfort.

AMPUTATIONS IN PERIPHERAL VASCULAR DISEASE

When amputation is found necessary for intractable pain or for advancing gangrene the choice of a site for such amputation is a difficult matter.

Much depends upon the cause of the gangrene whether entirely circulatory in origin or due to a combination of infection and vascular occlusion (McKrittrick). In the presence of advancing infection delay in amputation may be fatal. The site of ampu-

tation is usually above the knee. On the other hand in a case of gangrene and infection limited to one or two toes with a palpable popliteal pulse the toes are amputated locally and accessory measures as already described are taken to improve the circulation.

In gangrene of the foot without serious infection and with a palpable popliteal pulse amputation below the knee may be attempted although it must be recognized that such an attempt is unsuccessful in about 20 per cent of cases. When the popliteal artery is not palpable a Callander amputation through the femoral condyles or preferably a very low thigh amputation may be attempted if vascular occlusion is due to arteriosclerosis. If due to thromboangitis the collateral circulation may warrant amputation below the knee. Clots found at operation in the main vessel may be removed by the introduction of a soft rubber catheter through which salt solution is introduced and the clots washed out.

Assistance in determining the site for amputation may be gained through the hyperemic test of Moschcowicz. The affected limb is elevated long enough to obtain pallor of the skin. A broad elastic bandage is applied as high as possible and sufficiently tight to obstruct the artery. This remains in place for from three to five minutes. When it is removed a hyperemic blush spreads rapidly down the surface of the thigh but only within the well vascularized area. Pallor persists where the vascular supply is inadequate. Amputation should not be carried out through any pale areas of skin. The Moschcowicz test should *never* be performed in a limb deprived of its circulation except under conditions which permit immediate amputation. The test may precipitate or greatly accelerate gangrene.

In performing amputations for gangrene or incipient gangrene the use of a tourniquet is absolutely contraindicated (1) because of danger of traumatizing already diseased vessels and precipitating thrombosis at the site of compression and (2) because of fear of causing death of tissues already deprived of adequate nutrition. The greatest gentleness is observed in handling tissues and individual bleeding vessels are grasped with small arterial clamps rather

than with large hemostats so as to avoid strangulating large masses of muscle or fatty tissue. The less traumatized and dead tissue in a wound the more apt it is to heal by first intention. Sutures in muscle are unnecessary and only a few need to be placed in the fascia. The skin is loosely approximated without drainage.

In cases of gangrene of the leg in elderly debilitated patients amputation is most safely performed under refrigeration anesthesia. The entire leg is surrounded with ice bags for two and one half to three and one-half hours when anesthesia is usually complete. For the very aged patient refrigeration may be curtailed to one or two hours and supplementary gas anesthesia employed. In the presence of gangrene and infection refrigeration may be applied immediately upon the patient's admission to the hospital while further studies are being completed. Refrigeration keeps the infection in abeyance, prevents further toxemia and minimizes shock when amputation is done.

ANEURYSMS

Once forming a frequent problem in a surgeon's practice aneurysms are becoming more or less rare and give promise of occurring even less frequently. The more adequate treatment of syphilis may account for this change.

An aneurysm is a pulsating sac containing liquid or coagulated blood or both and is directly connected with the lumen of an artery. Such a sac may be the result of injury to the artery—a traumatic aneurysm. It may also follow the disintegrating action of syphilis or of arteriosclerosis on the arterial wall resulting in the so-called spontaneous idiopathic or pathologic aneurysm. In such a case the media the strong elastic coat of the artery has been destroyed and replaced by fibrous tissue or

calcareous deposits. Under the stress of exertion or emotion the intra arterial pressure may be greatly increased and the scarred wall may give way to form a fusiform swelling in the course of the artery the intima and adventitia of which may still be intact. This is known as a *true aneurysm*. However such an increase in intra arterial pressure may also produce a pouch projecting from the side of the artery which gradually enlarges and which may even burst into the perivascular tissues to form a *false* or *sacculated aneurysm*. Rarely in the thoracic aorta the giving way of the intima and media permits the blood to escape from the lumen into a potential space between layers of the media thus resulting in a dissecting aneurysm which follows along the course of the artery for a variable distance. Left to itself an aneurysm invariably continues to expand and death occurs either from pressure on some vital structure or from massive external or internal hemorrhage. As the aneurysmal dilatation approaches the skin it may present all the evidences of inflammation and abscess. Rarely spontaneous cure occurs due to clotting of the stagnant stream in the aneurysmal sac a fortuitous event which practitioners in the past have attempted to encourage by the so-called Valvula treatment the essentials of which were absolute rest starvation blood letting and abstention from fluids.

Mycotic Aneurysm—An infected embolus may give rise to a localized abscess particularly if it has its origin in the periphery and lodges in the brain where abscess or meningitis may develop. Small clumps of bacteria originating in vegetations of the endocardium accompanying bacterial endocarditis may lodge in the vasa vasorum of large arteries producing destruction of the arterial wall and the development of a so called mycotic aneurysm. Occasionally multiple dilatations due to mycotic aneurysms occur. On rare occasions the infectious process beginning in the wall of the artery involves also the contiguous vein and a mycotic arteriovenous aneurysm is the result.

Symptoms—Symptoms are extremely variable depending on the location and size of the aneurysm. The most frequent site is in the thoracic aorta where it may produce pain from an erosion of vertebral ribs or

sternum dyspnea and cough from pressure on the air passages hoarseness from paralysis of the left recurrent laryngeal nerve due to pressure or stretching as it passes under the arch of the aorta Aneurysms of the ascending aorta may cause incompetence of the aortic valves with all the symptoms of regurgitation including collapsing pulse and cardiac hypertrophy In contrast with the remarkable dilatations of the heart observed as a sequence to an arteriovenous aneurysm the fusiform or sacculated aneurysm has in itself little effect on the heart unless it happens also to produce aortic incompetence An associated generalized arteriosclerosis may be the cause of the cardiac hypertrophy erroneously ascribed to the aneurysm A thoracic aneurysm may rupture into the thorax into the trachea or externally through the skin Rupture of an aneurysm into a cavity may produce great pallor intense weakness unconsciousness and finally death

Innominate subclavian and carotid aneurysms present in the neck where localized pressure on the brachial plexus may produce sensory or motor paralysis of the arm Pressure on the cervical sympathetic plexus may produce Horner's syndrome namely a contracted pupil and a narrowed palpebral fissure Vertigo faintness and attacks of unconsciousness may accompany a carotid aneurysm

Aneurysms of the internal carotid within the skull may produce symptoms of a brain tumor Numbness of the face unilateral oculomotor palsies and headache should suggest an intracranial aneurysm of the internal carotid artery (Symonds)

Aneurysms of the extremities because of their accessibility exhibit distinctive features The swelling is not only pulsating but expansile *i.e.* palpation by the two index fingers shows separation of the fingers with each systole of the heart Pressure on the artery above the aneurysm may cause it most complete disappearance of the swelling The blood pressure readings below the aneurysm are lower than similar readings on the unaffected side

Aneurysms of the femoral or popliteal arteries may interfere with venous and lymphatic return and produce swelling of the limb Diminished circulation below the aneu-

rysm may produce symptoms of peripheral ischemia such as absent pulsation intermittent claudication and rest pain The popliteal aneurysm which may be the result of the constant trauma of flexion and extension on a rigid arteriosclerotic arterial wall is often accompanied by considerable pain and disability on walking

Aneurysms usually exhibit on auscultation an interrupted bruit which may be systolic only or both systolic and diastolic with a definite hiatus between the two phases

Differential Diagnosis—Highly vascular tumors such as certain sarcomas simulate aneurysms so exactly even to the production of systolic bruits that the differential diagnosis is difficult A tumor of the carotid body which is highly vascular and uniquely situated between the branches of the common carotid artery is frequently diagnosed as a carotid aneurysm

A cyst or tumor over a large vessel may transmit such a vigorous pulsation that it is difficult to rule out aneurysm

Great care must be exercised in differentiating a simple aneurysm from an arteriovenous aneurysm inasmuch as ligation of the artery proximal to the latter lesion—on the basis of a mistaken diagnosis of simple aneurysm—will in most instances lead to real circulatory embarrassment if not to gangrene of the extremity The continuous thrill and bruit the prominence of veins in the neighborhood of the fistula the slowing of the pulse and increase in blood pressure on closing the fistula by digital compression or on compressing the artery proximal to the aneurysmal mass should serve to identify the arteriovenous lesion The blood pressure and pulse are unaffected by closing the artery proximal to a simple aneurysm

Treatment—Medical measures designed to decrease intra arterial pressure and promote spontaneous clotting by stagnation of the blood stream are usually unsuccessful Limitation of foods and fluids and complete rest may relieve pain but do not cure the lesion The various methods of ligation of the artery proximal to the aneurysm depend on a decreased pressure and clotting within the sac for their curative effect a result not always achieved because of the development of collateral circulation Historically specific

names have become identified with certain ligations. Antyllus a Roman of the third century is credited with having ligated the vessel proximal and distal to the aneurysmal sac following which the sac was opened and evacuated. Acl of Toulouse in 1710 described ligating the artery just proximal to the sac whereas in 1786 John Hunter first employed his classical operation in Hunter's canal for a popliteal aneurysm. Acl's ligation is performed at a site likely to be involved in the pathologic process whereas the hunterian ligation is performed at a point where the vessel wall is normal thus reducing the danger of erosion of the wall and secondary hemorrhage at the site of the ligation.

sac by scratching it with long fine needles introduced from without. Clotting is accelerated thereby and may be used with or without ligation of the artery proximal to the aneurysm.

All ligations have an inherent defect—they do not attack the aneurysmal sac directly. Extirpation of the sac has been repeatedly advocated but the dangers are real. Adjacent structures such as nerves may be so intimately bound to the sac that its excision would endanger the distal nerve supply. Moreover such excision would also endanger the collaterals present in the tissues surrounding the aneurysm. Both the defects are remedied by the excellent operation of Matas first used by him in 1889.

A

B

Fig 82—Aneurysmorrhaphy according to Matas. A Obliteration of aneurysmal sac by successive layers of sutures. B Restoration of arterial lumen by closure of distal opening and obliteration of sac.

Brasdor a French surgeon in 1760 advised ligating the artery distal to the aneurysm. If there are no branches of the vessel between the aneurysm and the distal ligation this should be an excellent procedure inasmuch as Halsted has shown that there is very little pulsation in the part of the vessel lying between the ligature and the first branch proximal to the ligature. This being true there should be little pulsation in the aneurysmal sac which lies proximal to the ligature. Distal ligation is applicable to aneurysms of the aorta and the three main carotid and subclavian arteries.

Macawee of Glasgow suggested traumatizing the inner surface of the aneurysmal

sac and since applied with remarkable success in many hundreds of cases (Fig 82). The operation depends on the feasibility of completely controlling all circulation through the sac by the application of a tourniquet or by the application of arterial clamps to the vessel proximal to the sac. In the case of a fusiform aneurysm the sac is boldly opened the clots are removed and both arterial orifices and all branch openings are closed by individual transfixion ligatures. The sac is then obliterated by successive rows of ligatures applied to the sac. This he entitled the obliterative aneurysmorrhaphy. The sacculated aneurysm is also boldly entered and occasionally the opening from the artery itself can be sutured and

its closure reinforced by suturing the walls of the sac over it. This was called *restorative endoaneurysmorrhaphy*. When preservation of the main channel would seem necessary for the life of the limb Matsis advocated the *reconstructive endoaneurysmorrhaphy*. The continuity of the parent artery may be restored by making a new channel out of the sac walls which can be brought together by suture over a guide (catheter or drainage tube) inserted into the proximal and distal openings of the aneurysm. Before the last suture is tied the guide is removed and the channel is left behind corresponding to the outline of the original artery. Even though such a passage may ultimately close by clotting the temporary assistance to circulation through this restored artery may be sufficient to prevent gangrene.

Operations for the cure of a carotid aneurysm are attended by the danger of fatal interference with the nutrition of the brain particularly in adults. Halsted therefore devised the method of partially occluding the large vessels proximal to the aneurysm by the application of an aluminum band which could be removed subsequently if hemiplegia of the opposite side gave evidence of cerebral anemia. Erosion of the arterial wall under the aluminum band is an ever present danger. Less dangerous is a narrow strip from the fascia lata which may be employed for partial occlusion by wrapping it twice around the artery and suturing the ends together (Brooks). The same precautions concerning the ligation of arteries should be observed as were enumerated earlier.

VARICOSE VEINS

Definition.—Tortuous segmental dilations of veins may occur anywhere in the body. Some such as varices of the upper extremities and of the central nervous system, esophageal varices in portal hypertension, varices of the broad ligament and urinary bladder, the varices of the spermatic

veins as varicocele and the enlargement of the rectal veins as hemorrhoids may produce characteristic clinical symptoms. In this discussion however only the superficial venous system of the lower extremities, namely the involvement of the saphenous network, will be considered (Fig. 83).

Incidence.—It is difficult to estimate the incidence of varicose veins with a fair degree of accuracy. However in a thorough examination of 1000 young healthy industrial

Fig. 83.—Infra-red photograph of lower extremities. There is valvular incompetence between the right long saphenous vein and the deep veins system below the knee. Above the knee and over the entire left leg the normal subcutaneous pattern of the saphenous system is well visualized. With the exception of a small varicosity on the right calf, no veins were visible in an ordinary photograph.

workers, 10 per cent were found to have been affected. Varicose veins were noted in 40.7 per cent of the men and 73.2 per cent of the women employed in a large department store (596 employees). All were over forty years of age.¹

Etiology.—The saphenous network has been put to an unusual strain through the erect posture of man. Adaptation to the erect posture is accomplished by means of many valves which relieve the lower ex-

tremitics from venous backflow. That the adaptation is not uniformly adequate is shown by the marked variations in the number and position of the valves. In addition the anatomic course of the saphenous vein deprives them of an important aid in venous return, namely the milking effect of muscular activity. As the veins are unsupported between the skin and the fascial layer an increased venous pressure may readily produce anatomic changes.

Heredity seems to be important in the development of varicose veins. A constitutional weakness of the connective tissue is often seen in patients afflicted with varicose veins. Such patients have hernias, flat feet, frequent nosebleeds because of varicosities of the nasal septum or cutaneous nevii; they are asthenic and have a low blood pressure. If both parents are afflicted their children usually have varicose veins in the early twenties.

A second factor in the production of varicose veins is the undue strain of prolonged motionless standing on the saphenous system. Thus waiters, laundresses, street car conductors and policemen are predisposed by occupation and their existing varicosities are aggravated. Other causes for increasing venous hypertension are traumatic rupture of valves constricting garters, pressure of enlarged lymph glands or pelvic organs, straining with constipation and pregnancy. This last factor is so important that it requires further elaboration. Pregnancy interferes with the venous backflow from the lower extremity by the pressure of the greatly enlarged uterus on the iliac veins. But more important than this is the greatly increased volume of venous blood flowing from the hypogastric vein which produces a relative incompetence and obstruction in the external iliac vein. Thus varicose veins may become manifest and painful in the first third of pregnancy when the size of the uterus could hardly account for the venous obstruction.

Finally the effect of postpartum postoperative or postinfectious thrombophlebitis on the development of varicosities must be considered. The obstructive clot may be manifest or latent according to its extent and location but it will produce a new collateral circulation with the formation of

varicosities of atypical course. The clots may be in any segment of the venous system including the veins of the calf and thigh muscles. If this clot later canalizes and the circulation is re-established there still remains the effect of the destruction of important valves in the veins. The patient then suffers from a valvular incompetence with resulting postural venous hypertension.

Accordingly the following factors are important in the etiology of varicose veins: heredity, trauma, increased postural strain, compression or constriction of veins and phlebitis which may destroy valves in the superficial or deep venous system. All of these factors induce a postural venous hypertension of the lower extremities which is the pathologic equivalent of varicose veins. Whether the valvular incompetence is primary or not, it is directly responsible for the pooling of blood in the dependent extremities.

Pathology.—The changes encountered in varicose veins are the results of increased venous pressure on a muscular tube which first responds with hypertrophy and later with dilatation, elongation and tortuosity. There is a more or less constant inflammatory reaction in and around the walls of varicose veins indicating that bacteria which were in the blood stream have lodged in the sluggish pools where drainage is slow and incomplete. The thinning and sacular or spindle shaped dilatation of the veins occurs at first just proximal to the valves and then spreads distally. As a result of the loss of muscular elements by continuous distention and often infection a fibrosis or even a scleritis with lime deposits takes place. The phlebosclerosis in senility is an analogous arteriosclerosis and gives a striking x-ray picture of the lime deposits.

When the venous stasis spreads from the large veins into the subcutaneous network or into the intradermal subpapillary plexus the so-called spider bursts or rocket bursts appear. A supramalleolar cyanosis seen often in women of asthenic slender build and endocrine dysfunction such as low metabolic rate and scant menstrual flow is a sign of such progressive venous insufficiency. It is markedly aggravated in pregnancy.

Symptomatology—The early symptoms of progressive venous insufficiency are a tired heavy sensation in the legs cramping of the calves at night or in cold water and swelling of the ankle or dorsum of the foot. When the venous dilatations reach a certain stage the pressure and traction on the accompanying saphenous nerve may produce painful radiation along the course of the nerve. The extent of the varicosities by no means parallels the severity of symptoms as enormous dilatations are often

blood in the dilated veins is arterial in character this being recognized by the light red color of oxygenated blood. Compensatory venous dilatations following deep venous thrombosis are not true varicose veins and do not follow the course of the internal and external saphenous veins but show atypical convolutions chiefly on the lateral aspect of the thigh, lower leg and dorsum of the foot.

A most important error is to diagnose varicose veins as a cause of complaints when

TRENDELENBURG TEST

Fig. 81—Trendelenburg test. The leg is first elevated to empty the vein and constriction is applied. Then pressure is exerted to collapse only the superficial veins. The patient then stands up. If the pressure is maintained, note the collapse of the veins. If the vein does not collapse when pressure is applied at the groin, it may still be made to collapse when pressure is applied at lower levels, below incompetent communicating valves on the thigh. The fourth sketch shows the leg immediately after the pressure of the band has been released. Note the sudden filling of the veins from above.

symptomless and a few hardly palpable varicosities may produce much discomfort. Most of the symptoms, however, are due to complications such as phlebitis, ulceration, eczema or superimposed skin infection.

Diagnosis—If every dilated vein on the lower extremities is regarded as a varicose vein and treated as such, grave mistakes may occur. Multiple arteriovenous fistulas are easily mistaken for varicose veins. These are congenital, slowly progressive lesions. The affected limb is warmer and sometimes larger than its fellow, and the

other conditions are responsible for the symptoms presented. Thus static deformities, flatfoot, genu valgum, sacroileal or lumbosacral arthritis, spondylolisthesis, or true scurvy may be overlooked in the presence of a few insignificant varices. Almost any traumatic, infectious or neoplastic disease may simulate the vague symptoms of varicosities and may be overlooked during a superficial examination.

Soft, fluctuating, easily compressible masses on the lower extremities may be diagnosed erroneously as varicose veins. Of

these, femoral hernia the rare lymphocele and small muscle hernias which occur on the lateral aspect of the lower leg in young athletic persons should be mentioned.

A diagnosis of varicose veins is not complete until the condition of the superficial and communicating valves and the patency of the deep veins are determined. The Trendelenburg test (Fig 84) gives information regarding (a) the incompetence of the saphenous valves and (b) the efficiency of the communicating valves at different levels.

ciency, it requires more intensive treatment and is more likely to recur.

The patency of deep veins is tested by the method of Perthes (Fig 84). Following constriction of the saphenous trunk by a tourniquet vigorous muscular exercise is carried out. blood is sucked into the deep veins and the superficial varicosities collapse. When the pressure is released the filling from above demonstrates the amount of blood aspirated into the deep veins. If the deep veins are not patent or if there is

Fig 85.—Perthes test. A tourniquet is applied at different levels with the patient in the standing position. Vigorous flexion and extension of the knee is carried out ten times. Note how the veins collapse after exercise indicating patency of the deep veins. When the pressure is released the veins suddenly fill from above. The tourniquet may be placed around the thigh at different levels and thus localizes the level of incompetent valves in the communicating veins.

When after elevation and digital or circular compression of the saphenous trunk the veins in the calf remain collapsed in the standing position, one has good evidence that reflux of venous blood occurs only from above, i.e. through the saphenofemoral junction and not from the deep veins through the communicating branches. When however in spite of saphenous compression the veins of the calf suddenly fill when the erect posture is assumed the communicating valves are incompetent. This is a more advanced stage of venous insufficiency.

an increased venous pressure in the deep veins on standing no diminution of the superficial veins will take place. The test not only denotes patency of the deep veins when the veins collapse during exercise but also localizes the site of incompetent veins on the thigh when applied at different levels. Thus it becomes a modification of Mahomed and Oelsner's comparative tourniquet test.³

Deep venous obstruction results from ascent to the iliofemoral segment of propagating thrombi from the deep and communicating veins in the foot and calf. This

groin Their greatest usefulness is in chronic indurated ulcers or postphlebitic indurations and they may be readily combined with surgical measures to reduce back pressure

Treatment by rest in bed elevation and hot boric acid dressings may become necessary in acutely inflamed ulcers The ulcers harbor many bacteria An azochloramide-sulfanilamide powder in an alkaline buffer is very helpful in clearing up this infection Within a few days however the patient may get up and walk Muscular contractions of the calf muscles and tight even pressure obtained by marine or rubber sponges under an elastic adhesive dressing will promote healing in a large percentage of ulcerations Should the ulcer fail to heal under such management one must consider (1) a disturbance of arterial circulation evidenced by absent or diminished pulses drop in skin temperature dependent rubor and pallor on elevation (2) the presence of a non varicose ulcer such as a thrombo phlebitic traumatic luetic mycotic or trophic ulcer or (3) the extensive induration around the ulcer which interferes with blood supply and the size of the defect which is not apt to heal spontaneously In the latter case excision of the ulcer and skin grafts are necessary Iontophoresis with histamine methyl or sodium chloride may help to soften the induration around the ulcer but is a very slow and cumbersome process

Injection Treatment—The injection of irritating substances producing endophlebitis thrombosis and obliteration of varicose veins is indicated for ambulatory patients There are few but definite contraindications to this form of treatment⁶ Certain systemic diseases such as a history of cardiovascular accident (angina pectoris cerebral thrombosis) hyperthyroidism active tuberculosis and acute infections of any sort prohibit the use of this method which may aggravate or activate the quiescent lesion A recent cold or tonsillitis in addition may produce thrombophlebitis originating at the site of injection Of the local conditions the lack of patent deep veins (see description of Perthes test) and the presence of a manifest or latent infection either in the deep or in the superficial veins are the definite con

traindications The solutions used are 50 per cent dextrose 15 to 30 per cent sodium chloride a mixture of 50 per cent dextrose and 30 per cent sodium chloride various concentrations of invert sugar sodium salicylate quinine and urethane and 5 to 10 per cent solutions of sodium morrhuate or potassium oleate The action of all these solutions is physicochemical injury to the endothelium of the vein which responds with an outpouring of fibrinous exudate and rapid organization of a mixed thrombus One should postulate for such a solution that it must be (1) non toxic in the amounts used (2) effective (3) not too painful and (4) not capable of producing extensive sloughs or (5) drug hypersensitivity While the ideal solution has not been found potassium oleate in 5 or 10 per cent solution injected in from two to four segments at a time in quantities of from 0.5 to 2 cc is the writer's choice at the present time

The criticism of this method is that while it readily obliterates visible and palpable segments below the knee and occasionally above the knee it does not reliably interrupt back pressure from the highest segment of the internal saphenous vein or from incompetent perforating veins and therefore is equivalent to local excision of varicose segments which is likely to be followed by recurrence Sloughs can usually be avoided by meticulous care in eliminating paravenous injections Should they occur immediate injection of the patient's own blood into the blanched area is helpful The fully developed slough is best excised followed by primary suture

Surgical Procedures—High ligation of the saphenous vein is first systematically employed to interrupt back pressure from above by Trendelenburg can be done under local anesthesia for ambulatory patients⁷ With a hookstick incision placed one-third above and two thirds below Poupart's ligament the internal saphenous vein is exposed doubly tied and cut The ligature is placed as close to the saphenofemoral junction as possible All tributaries entering the saphenous vein at or below the junction must be cut between ligatures (Fig 85) Failure to ligate the saphenous vein flush with its femoral junction results in complete canalization of the main trunk (Fig 86)

Fig. 88—High ligation of the long saphenous vein with retrograde injection. *A* The line of incision is marked out after careful soap and water preparation the night before. With a 2 per cent aqueous solution of brilliant green the line is drawn over the pulsation of the femoral artery gently curving medially 1 inch below and parallel with the inguinal ligament. This incision provides a good exposure of the saphenofemoral junction. *B* The superficial fascia has been split. The main saphenous trunk is exposed with several tributaries whose pattern is variable. *C* Two No. 20 cotton ligatures are placed 1 inch apart. The proximal ligature is tied; the distal is left loose and is used for traction when a No. 18 ureteral catheter is inserted into the vein. The catheter is marked in inches so that the length of the catheter which can be passed into the distal segment can be measured. The catheter may often pass as far as 26 to 30 inches into the vein. On its slow withdrawal approximately 1 cc. of sclerosing solution is injected for each inch of venous segment. The solution used is 30 per cent dextrose in 20 per cent salt solution. *D* After the catheter is withdrawn the distal stump is tied and a transfexion ligature is placed proximal to it. Then the proximal stump is grasped with a curved hemostat and all tributaries entering the vein between the proximal stump and its junction with the femoral are doubly tied with No. 40 cotton and cut. Finally the fossa ovals and the femoral vein proximally and distally to the junction are exposed and a No. 20 cotton ligature is placed flush with the junction. No saphenous pocket must be left since a thrombus may form and break loose. Distal to the ligature the vein is transfixed with a suture-ligature to insure against slipping. The subcutaneous fascia is carefully closed with No. 60 cotton sutures and the skin is closed with interrupted black cotton sutures. In hot weather sulfanilamide powder is dusted over the line of suture and the dressing secured by three to four strips of elastic adhesive tape.

The ligatures are anchored by transfexion sutures to insure against slipping. The ambulatory, high saphenous vein ligation may

be carried out on all patients who show a visible or palpable reflux from above on the thigh and whose deep veins are patent. The

operation is also done on patients with varicose ulcers provided there is no acute infection present. It reduces the percentage of recurrences, reduces the number of necessary injections and serves as an efficient barrier against embolism should an ascending thrombosis develop in the saphenous vein and spread toward its junction with the femoral vein.

In the absence of any latent phlebitis (discussed in the following section) a sclerosing solution is injected into the distal

Fig. 80—Ligation of the long saphenous vein was done with a transverse incision too low to catch some of the tributaries. Two years later the patient presented a complete recurrence in the saphenous vein and its tributaries. The recurrence occurred through the unligated tributaries. The line of incision and the visible tributaries are marked with mercurochrome. Such cases require reoperation.

stump at the time of the operation. A ureteral catheter passed gently as far as it will go evenly distributes 20 to 30 cc of a dextrose salt mixture. This usually obliterates the segment of saphenous vein to the knee. Injections are then continued a week later below the knee.

High saphenous ligation followed by injection treatment is the method of choice at present. Faulty technique of ligation overlooked incompetent communicating valves or incompetent short saphenous veins and

unrecognized damage to the deep venous circulation are responsible for the failures of this method.⁸ In a small percentage of cases multiple incompetent communicating veins below the knee may call for their subfascial ligation.⁹

After treatment following any type of procedure should consist of frequent inspection of the patient during the first few years. Small recanalizations or new varicosities can be easily reinserted. If the patient's occupation can be changed to one which is conducive to less mechanical strain the chances of permanent cure are enhanced.

VENOUS THROMBOSIS

The true incidence of thrombi in the vascular tree is easily underestimated since small segmental clots need not produce clinical symptoms. Even the pathologist may miss them unless he makes a deliberate search in certain areas which are usually not examined in a routine postmortem examination. The plantar veins of the foot and veins of the calf muscle harbor thrombi in 50 to 60 per cent of all adults.¹ The pelvic veins are frequently filled with phlebotitis visible in roentgenograms. The broad ligament when transected during hysterectomy

tomy, often contains plugged veins. The exact incidence of pelvic thrombi including those in the large vesical, uterine, prostatic and rectal plexuses has never been accurately estimated. While the majority of thrombi occur in the lower extremities and the pelvis, the upper extremity and any visceral organ may contain silent thrombotic areas which may become the starting point of massive clinically manifest occlusions.

Etiology.—Three factors, namely, slowing of the circulation, trauma to the intima and increased tendency to clotting can be readily recognized as being responsible for the localization and production of intravascular clotting. Many other contributory or predisposing factors operate through these three main channels.

1 Slowing of Circulation.—When circulating blood slows down its corpuscular elements group themselves into a central axial current containing mainly red cells, the white blood cells take a more peripheral position, whereas the platelets seem to travel at the periphery, sweeping the intimal surface. Clumping of platelets or adherence to the intima can immediately take place whenever a raw surface is encountered. Nevertheless, stagnation of blood alone need not give rise to thrombosis. Blood may stay liquid in a vein between two ligatures if care is taken not to injure the intima, but when other factors are present the ligatures will serve to localize the clot to a certain segment. The postoperative state and the slow circulation time of the cardiac patient predispose to thrombosis; the constricting action of ligaments and tendinous insertions may determine the localization of the thrombus. Thus the lateral plantar veins of the foot are crossed and readily compressed by the plantaris longus tendon, the upper margin of the soleus muscle or Poupert's ligament has a retarding action on venous return, especially in certain positions.² The left common iliac vein possesses a congenital stricture, thus explaining the more frequent involvement of the left lower extremity.³

2 Injury to the Intima.—Mechanical trauma such as tearing or stretching of a vessel is responsible for thromboses following sprains, fractures, gunshot wounds and stab wounds. The vessel itself does not have

to be cut through to show injury of the endothelial lining. But here again the bruise of the lining alone will not suffice to produce a massive propagating thrombus unless another factor, namely, the outpouring of tissue juice is added. Injury to the intima also occurs in infections or degenerative lesions of the vessel wall interfering with the nutrition of the inner coat. Such lesions are encountered in infectious arteritis and phlebitis in Buerger's disease or at the site of subintimal atheromatous plaques which ulcerate and produce sessile thrombi on their roughened surface. Vascular sensitization seems to play an important role in setting up an allergic inflammation, notably present in periarteritis nodosa;⁴ such a lesion may terminate in thrombosis or the formation of small aneurysms. Aneurysms themselves, whether congenital, traumatic or infectious, are a frequent source of mural thrombi which occasionally lead to spontaneous obliteration of the sac.⁵

3 Increased Tendency to Clotting.—There are many conditions which produce increased coagulability of the blood. Loss of plasma in burns and in secondary shock, dehydration due to vomiting and rapid diuresis after use of mercurials produce hemoconcentration and increased viscosity; the same is true in patients with polycythemia whose clotting tendency is notorious. Fundamentally, any lesion which liberates thrombokinasase will accelerate blood clotting. This occurs after injuries to tissues, especially muscles, massive wounds of the extremities or surgical trauma producing increased coagulability. In the blood itself the destruction of platelets liberates thrombokinasase so that every agglutination of thrombi of platelets carries in itself a nucleus for further spread of thrombosis. Patients suffering from erythematosis⁶ or from excessive digitalization⁷ show an acceleration of the clotting mechanism.

Prevention of Thrombosis.—Increased attention to the three factors just described may help to decrease the incidence of thrombosis. Postoperatively the patient should be placed in a Trendelenburg position (6 to 8 inches of elevation of the foot of the bed). He should be encouraged to take regular breathing exercises and he should flex and extend his foot and calf mus-

cles many times a day. He should not be kept in bed any longer than absolutely necessary. Statistics amply prove that with identical groups of patients those who are ambulatory earlier show a lower incidence of thrombosis. Obviously all such measures have their contraindications and limitations.

Fig 90—Note that heparin acts by counteracting the effect of thrombinase and by preventing the conversion of prothrombin to thrombin. Whether heparin also acts on the second phase of clotting, namely the conversion of thrombin into fibrinase, is doubtful.*

Trauma of course whether mechanical, thermal or bacterial is impossible to prevent but once it affects the vessel by thrombosis the propagation of the clot can be arrested by measures to be discussed in the next paragraph.

bleeding time may reveal some changes but are not sensitive enough. Since heparin acts by inhibiting the first phase of blood clotting (Fig 90) the individual's response to heparin can be used to measure the amount of clotting factors in the blood. Ten milligrams of heparin will produce a typical curve in the normal individual when such a curve is flattened he either harbors thrombi or at least his blood is more readily coagulable so that he requires increased protection (Fig 91).

Whether such clotting really runs in families is uncertain but it is known that some operations and some preoperative conditions carry an incidence of thrombosis that is higher than average. A patient who undergoes laparotomy, prostatectomy or an operation on or fracture of the hip especially if he is old or obese is in the endangered group. If he has previously had a thrombosis the risk is approximately doubled.⁹ Such a patient is entitled to the prophylactic administration of heparin or dicoumarol (See the section on Treatment).

Pathology—Thrombi are classified as being hyaline, red or white. The first are found in smaller vessels and represent glassy fibrinoid masses occurring as a result of toxic

Fig 91—Note that in cases of acute thrombosis the response to 10 m^g of heparin is either absent or very poor, whereas in the chronic cases the same amount of heparin produces a marked increase in the coagulation time over the period of forty minutes. The flattening of these heparin curves is also observed in the first few days after a major operation, after sudden dehydration or after toxic losses of digests.[†]

Excessive coagulability of the blood can be counteracted by the judicious use of anti-coagulants.⁸ In order to use such drugs in their proper place there is need for simple rapid detection of an increased clotting tendency. The customary clotting time and

injuries to the intima. They may become the seat of superimposed red, white or mixed clots.

Red thrombi occur as a result of the coagulation of stagnating blood. They are practically identical with a postmortem clot.

* de Takats, Surg. Gynec. & Obst. 77.

† de Takats, Surg. Gynec. & Obst. 77.

and consist of large masses of red cells and some leukocytes embedded in a network of fibrin. Their surface is smooth, their consistency soft and spongy, and they are rarely adherent to the vessel wall, at least in the early days of their formation. They occur secondarily following the formation of a white clot which produces an obstruction to the blood flow and liberates massive amounts of thrombokinase. Red thrombi are most important from the standpoint of embolism.

White thrombi, in contradistinction to the red thrombi, occur in the circulating blood and typify the agglutination thrombi of platelets. The platelet thrombus is soon covered by a layer of leukocytes and fibrin, thus giving rise to the white or leukocyte thrombus. Their surface is rough and granular, and they are much firmer and contain less water than do the red thrombi. They adhere firmly to the wall of the vessel at the site of an intimal lesion.

Progression of Thrombi.—The white thrombus, commonly called the head of the thrombus, if it obstructs the vessel completely, may give rise to a superimposed red thrombus, the tail of which may lie in the veins either peripherally to the head of the clot, in which case it obstructs distally important collaterals, or centrally, in which case the end may become loose and produce an embolus. Usually there is a transitional segment between the head and tail, a mixed thrombus consisting of the mixture of red and white thrombi. When the tail of a thrombus breaks off, another red thrombus may quickly reform. This propagating thrombus, whether it forms in the vein or in the artery, is the most significant complication of intravascular clotting.

Symptomatology.—No attempt will be made here to discuss the symptomatology of visceral thrombosis, only venous occlusions of the upper and lower extremities and of the pelvis will be described.

A. Thrombosis of the Upper Extremity.—*Axillary thrombosis* (thrombosis on effort) affects muscular young men, who after sudden, violent exertion, experience a sharp pain in the axilla or anterior chest wall, followed by swelling and cyanosis of the entire upper extremity. If not relieved by appropriate measures, the swelling becomes rather

fixed. The superficial veins stand out prominently, and a cutaneous network of collaterals develops over the shoulder girdle. If the arm is exercised, it becomes numb and painful, and the venous pressure visibly increases in the superficial veins. The obstruction is usually in the subpectoral segment of the subclavian vein, where it becomes compressed between the anterior chest wall and the costocoracoid fascia. The level of obstruction and the extent of the collateral circulation can be readily visualized by inject-

Fig. 92.—Roentgenogram of a young man who suddenly developed pain and swelling of the right arm during basket ball practice. After injection of 20 cc of diodrast into a prominent cubital vein complete block of the third portion of the subclavian vein just below the clavicle becomes apparent. Collateral circulation was evident over the shoulder and scapula.

ing radio-opaque solution, such as 35 per cent diodrast, into a superficial vein at the elbow. A roentgenogram is obtained of the axillary region within thirty seconds (Fig. 92).

While this lesion is obviously of traumatic origin, other factors, such as infectious periphlebitis originating from an infected hand or a polycythemia resulting in increased coagulability, have been recognized as contributory causes.

Another type of axillary venous thrombosis is encountered following radical mastec-

tomy for carcinoma of the breast. The marked edema of the arm following such an operation may be due to lymphatic or venous obstruction or to a combination of the two.¹⁰

Because of the extensive use of intravenous injections and continuous drips the superficial veins at the elbow or on the dorsum of the hand not infrequently show a short segmental thrombus which is of little import unless it shows proximal spread toward the axilla. In such cases marked periphlebitic induration is also manifest. Emboli from such a source are most unlikely. More serious is a perivenous leak from some irritating solution toward the median nerve which may give rise to a long lasting cruralgia state.¹¹

B. Thromboses of the Lower Extremity

—1 THROMBOSIS OF SUPERFICIAL VEINS—Varicose veins frequently harbor a latent infection and slight trauma, the puncture of a needle or the introduction of a sclerosing solution may reactivate a resting infection.¹²

In other cases the infection is frankly hematogenous originating in an infected tonsil or tooth and often following their removal. The large clots are hot and tender, they may start at any point but usually have an ascending character. The temperature and white blood cell count are seldom elevated and the leg shows no diffuse swelling except for localized edema around the inflamed vein.

A migrating segmental phlebitis of superficial veins that were previously not enlarged is highly suspicious of thrombophlebitis obliterans (See section on Thrombophlebitis Obliterans). Large superficial varicosities may also become thrombosed in the presence of an old deep venous obstruction. Such thromboses may affect the collateral venous pattern of the lower part of the leg thigh and anterior abdominal wall.

2 THROMBOSIS OF THE DEEP VEINS OF THE FOOT AND LOWER PART OF THE LEG—The plantar veins of the foot and the veins of the calf muscle harbor small thrombi in approximately half the adult population. Such clots become clinically manifest when they grow by apposition following the appearance of some other factor such as trauma, infection, immobilization or increased coagulability of the blood. In throm-

bosis of the plantar vein the sole of the foot especially the lateral side is tender to pressure. Later the tenderness may be extended over the inner malleolus and still later along the course of the posterior tibial vein. Pain and muscle spasm in the calf are noted when the foot is dorsiflexed (Homans sign).¹³ The temperature of the skin over the calf muscles is elevated if an oscillogeter is available it frequently reveals increased pulse waves over this area. The process may extend into the popliteal vein after which edema becomes manifest. Otherwise because of the abundance of deep veins in the lower part of the leg swelling does not appear. Hanging both feet over the edge of the bed for several minutes may reveal a cyanotic hue on the affected side.

Visualization of the deep veins of the lower part of the leg by radio opaque substances is unnecessary in the majority of cases. Only when a pulmonary embolus has formed and the source of the embolus is not apparent by simple clinical methods should such a diagnostic procedure be undertaken, even so the interpretation of the films at this area is often inconclusive (Fig 93).

Iliofemoral thrombosis is well known as milk leg. The clot has now ascended from the calf through Hunter's canal to the inguinal ligament or has extended from the hypogastric vein to its fusion with the external iliac vein. It practically never seems to form primarily at this level. There is sudden pain at the groin with diminution of arterial pulsation within twenty-four hours. Edema develops at first showing more of a venous cyanotic color and readily pitting. Later being a hard white lymphatic type of swelling. Unless adequately treated the occlusion may extend to the other limb in a high percentage of cases. Embolism from this level is infrequent.⁹ Such thrombi usually occur several days after the onset of thrombosis in the plantar veins in the muscles of the calf or in the pelvic veins. Close attention to the early signs and symptoms may avert the clinical picture of full blown iliofemoral thrombosis.

Thrombosis of the Pelvic Veins—A glance at the wide tortuous sinuses of the hypogastric vein, their difficult drainage over the sacral concavity, their proximity to frequently infected organs such as the blad-

der, uterus, prostate and rectum, explain the frequency of phleboliths in the roentgenograms and the mobilization of such clots after surgical procedures. The clinical symptoms of pelvic thromboses are vague, but they relate to the organs which they accompany. There may be pain and swelling of the buttocks or in the adductor muscles close to the inguinal fold. Sciatic neuritis is characteristic of a thrombosed sciatic vein. Frequency of urination or rectal spasm may denote thrombosis of the perivesical or hemorrhoidal plexus, but obviously this symptom may signify many other conditions. More characteristic are slight suprapubic edema or palpable cords lateral to the uterus or prostate. Emboli are not infrequent as long as the thrombosis is intrapelvic and therefore clinically more or less silent, but they are not so likely when the thrombus has extended to the common iliac vein and has produced a "milk leg."

There are, of course, combinations and transitions from one group to another. Generally speaking, the more latent and bland the thrombus, the more readily it breaks loose. In fact, approximately 40 per cent of pulmonary emboli appear before the primary source becomes evident.¹⁴ Whether one can always differentiate between an infectious thrombophlebitis and a non-infected phlebotrombosis¹⁵ is doubtful. A traumatic or mildly infected thrombus may recede as a bland, non-adherent clot which breaks loose easily. A bland phlebotrombosis can develop into an inflammatory periphlebitis when it reaches the inguinal lymphatics, which frequently harbor infection. The amount of edema accompanying thrombosis depends on the extent of the blocked collaterals, on the periphlebitic lymphatic obstruction and on the vaso-spasm accompanying the venous occlusion. They may all be present in the same patient in varying proportions.

Treatment.—The objectives of treatment are threefold: first, to localize the clot to the site at which it becomes manifest, second, to minimize or inhibit the formation of persistent edema, and, third, to prevent passing of single or recurrent emboli to the lung. All methods of treatment must be viewed with these three objectives in mind.

1. *Elevation*—Raising the foot of the bed

on high blocks or on two chairs helps venous and lymphatic drainage from the lower extremities and pelvis. A pillow under the knee and lower part of the leg angulates the popliteal and iliofemoral segments and is worse than the horizontal position. The up-

Fig 93.—This patient exhibited marked incompetence of the perforator veins in the calf without any edema and without any history of a thrombotic episode. Opaque substance demonstrates large sacular veins in the muscles and under the skin. The deep veins show a ragged contour and a sudden decrease in the lumen just below the popliteal fossa. The diagnosis of deep venous obstruction is corroborated by this film.

per extremity can be hung from a Balkan frame or elevated on pillows.

2. *Bed Rest*—In cases of superficial phlebitis or in deep venous obstructions, which have been excluded from the circulation by division of the vein proximal to the clot, bed rest may be necessary for only a few days until the pain subsides. In a typ-

ical ease of milk leg the pulse and temperature must be normal for ten days before the patient is allowed out of bed

3 *Heat*—Heat cradles or hot fomentations relieve pain but are apt to increase the edema. The skin may blister easily with moderate heat. Ice packs frequently employed are also not harmless since tissue injury may occur. A snug elastic compression from toes to groin allowing free muscular movement is preferable.

4 *Mercurial Diuretics*—Mercupurin from 0.5 to 2 cc given intravenously especially

phlebitis. Its use is limited to cases in which there are superficial streaks of phlebitis which are hot and very painful to touch and to cases of iliofemoral thrombosis with inguinal pain and lymphadenopathy. The treatment is thus directed purely against the periphlebitis. Nothing is known about its action on the clot itself.

6 *Anticoagulants*—Heparin is now available in pure form and is comparatively free of reactions except that sensitization may occur.¹⁷ It can be administered by continuous intravenous drip given in such doses

Fig 94—This patient received 300 mg of dicoumarol the first day and 200 mg of dicoumarol the second day after amputation. On the third day the prothrombin time was lengthened to 50 per cent of normal and nothing was given until the end of the fifth postoperative day when 100 mg was used daily to maintain a somewhat higher than normal level of prothrombin. In elderly arteriosclerotic patients who may bleed easily from undetected sources such as the kidney, prostate or gastrointestinal tract, it is wiser not to maintain the customary levels of 60 to 50 per cent of the normal prothrombin time. This patient was moving about freely in a chair on the fifth day and was discharged on the tenth day following operation.

if preceded by acidifying drugs such as ammonium chloride or ammonium nitrate decreases thrombophlebitic edema very effectively.¹⁶ However, if the patient is suddenly dehydrated, his blood may clot more readily, thus assisting propagation of the thrombus. Since safer methods are available, use of this drug does not seem necessary.

5 *X-Ray Therapy*—Small doses of x-rays not exceeding 100 r and administered with a heavy filter at intervals of one week hasten the absorption of the periphlebitic exudate and decrease the size of the enlarged lymph glands which may accompany

that an eight to ten minute capillary coagulation time (three times the normal level) is maintained. It is equally effective and simpler to give 50 mg (5 cc) intravenously every four hours; the coagulation time may be determined once an hour for the first period to determine the varying tolerance of the patient to the drug.¹⁷ Simultaneously with the administration of heparin the oral use of dicoumarol is started: 300 mg the first day and 200 mg the second day. On the third day the use of heparin can be discontinued since the lagging action of the extract of spoiled sweet clover

(dicoumarol) now becomes apparent. The activity of dicoumarol is measured by daily determination of the prothrombin time. The prothrombin level must be kept between 50 and 80 per cent of the normal so as to keep the drug in effective, yet safe limits (Fig 94). Should the level sink to 20 per cent of normal or below normal blood transfusion or massive (100-200 mg.) doses of vitamin K may restore it to normal. Dicoumarol should never be administered without control of the prothrombin level. This type of anticoagulant therapy is used in all types of thrombosis as long as the patient is bedridden, this includes pulmonary emboli whose source is unknown or which cannot be plugged by proximal ligation such as for instance a right auricular thrombus. When a patient becomes ambulatory but shows recurrent attacks of thromboses, as a polycythemic patient may, doses of 300 mg of dicoumarol a week, with at least one prothrombin determination a week are capable of checking such attacks.

7 Paravertebral Sympathetic Block.—Any vascular occlusion, whether arterial or venous produces vasospasm not only in the collateral vascular bed¹⁸ but also in adjoining major vessels if they are wrapped in the same vascular sheath. Pain and edema in venous thrombosis are due in part to increased vasoconstriction in the affected limb, sometimes even in the contralateral limb, the degree of vasospasm seems to depend on the perivascular involvement, namely, that of the adventitial fibers. For this reason the bland, non-inflammatory thrombus produces much less vasomotor reaction than the irritative, inflammatory lesion. Most of the vasospasm is seen in the iliofemoral group, with an occlude within the vascular sheath which may abolish femoral pulsation entirely and give rise to a false diagnosis of acute arterial occlusion. In such cases the affected limb is colder, the pulsations are diminished or absent and a severe, vise like constriction is felt throughout the leg and thigh. The same picture is seen in axillary venous thrombosis. The block of the regional sympathetics produces a remarkable relief from these symptoms. The arterial and venous spasms disappear, the limb becomes warm and dry and the edema rapidly diminishes.

In many cases, however, there is an increase in temperature over the foot and lower part of the leg, in fact, this is one of the earliest symptoms of incipient thrombosis of the leg. The pulses are bounding, the oscillogram shows increased pulsations. Pain is slight or absent and seems to be due to the edema. In such cases there is no evidence of excessive vasoconstriction and sympathetic block is unnecessary.

The lumbar sympathetics are blocked with 1 per cent procaine to abolish vasomotor tone in the lower extremities (Fig 95). The patient is placed in a lateral position, the site of the injection uppermost. Three or four wheels are made 2 to 2½ fingerbreadths (perhaps 4 to 5 cm.) lateral to the midline and at the upper border of each spinous process beginning from above with the first. Each wheel should fall about over a transverse process. The wheels are made with procaine (1 per cent) and the aponeurosis is anesthetized. Each needle is first inserted about perpendicular to the plane of the back and should meet a transverse process at a depth of about 4 to 5 cm. (2 inches). It is then withdrawn to the level of the aponeurosis and redirected (higher or lower) more centrally at an angle of less than 25 degrees with the plane of the back. It is passed about 2 to 2½ fingerbreadths (4 to 5 cm.) deeper than the transverse process so that its point impinges against the vertebra in the retropleural space. When passed in this direction the point of the needle will remain lateral to the great vessels and may be reinserted to make contact with the vertebra more anteriorly. Through each of the four needles 5 to 10 cc. of solution is injected.

Sympathetic block is often useful in the late chronic type of thrombophlebotic edema, existing much in and varied degree of swelling on different days, subject to changes in the weather. These patients have a chronic fibrous scar around the thrombosed vein maintaining various degrees of vasospasm. Before stripping or excision of such a vein is contemplated a few paravertebral sympathetic injections should be given as they may bring lasting relief.

For block of the upper extremity the patient is placed on his side, the head parallel with or lower than the neck and the side of the injection uppermost (Fig 96). A spot is selected 4 to 5 cm. lateral to the midline opposite the seventh cervical spinous process (for the injection above the first rib). A wheel is made and the muscular (aponeurosis is anesthetized). The 2 cm. (4 inch) needle is introduced at an angle of 25 to 30 degrees with the plane of the back and somewhat caudad. It may strike at a depth of 5 to 6 cm. (1½ inches) the first rib or the transverse process of the seventh cervical vertebra. In such a case it must be redirected higher (more cephalad) or lower (caudad) as the case may be and at a point perhaps 2 cm. (1 inch) deeper than the rib should strike the side of the vertebral body. The needle must then be rotated in a slightly more lateral direction so that it scrapes the vertebral body. In any case it must pass with a depth of 2 mm. (about ½ inch) of the body lest the point enter the pleural cavity. Its point is passed about 1

cm ($\frac{1}{2}$ inch) past its last contact with the vertebra. Suction on the needle must always be made to exclude bleeding or entry into pleura or lung. On injection of 10 cc of procaine solution vasodilatation should be rapid and Horner's syndrome is to be expected. Should

any varicosities. The saphenous bulb may have to be cleared of thrombi by aspiration with a glass suction tube. Free flow of blood must be obtained from the femoral vein.

Fig. 20.—Paravertebral block of the lumbar sympathetic chain. The lumbar sympathetic trunks are blocked with 1 per cent procaine to abolish vasomotor tone in the lower extremities. The patient is placed in a lateral position on the side to receive the injection uppermost. Three or four wheals are made on the skin (perhaps 4 to 5 cm) lateral to the midline and at the upper border of each spinous process beginning from above with the first. Each wheal should fall about over a transverse process. The wheals are made with procaine (1 per cent) and the aponeurosis is anesthetized. Each needle is first inserted about perpendicular to the plane of the back and should meet a transverse process at a depth of about 4 to 5 cm (2 inches). It is then withdrawn to the level of the aponeurosis and redirected (1/2 or lower) more centrally at an angle of less than 30 degrees with the plane of the back. It is passed about 2 to 3 fingerbreadths (1 to 5 cm) deeper than the transverse process so that its point impinges against the vertebra in the retroperitoneal space. When passed in this direction the point of the needle will remain lateral to the great vessels and may be reinserted to make contact with the vertebra more anteriorly. Five to 10 cc of solution is injected through each of the four needles.

procaine be injected into the lung the patient tastes it (salty flavor) very quickly.

8 Division of the Vein Proximal to the Thrombus—This is clearly indicated for the saphenous vein if thrombi occur in preexist-

ing varicosities. The saphenous bulb may have to be cleared of thrombi by aspiration with a glass suction tube. Free flow of blood must be obtained from the femoral vein.

ing or tenderness in the thigh or if a pulmonary embolus has occurred and careful study reveals the primary source in the lower part of one of the legs [Tunc¹³ advocates ligation of the common femoral vein

of embolism from this source is low (6 to 7 per cent) The clot is in the process of organization and anticoagulant therapy holds it under reasonable control Whether ligation of the common iliac vein should be done

Fig 96.—The paravertebral block of the upper dorsal sympathetic chain. For the block of the upper extremity the patient is placed on his side the head parallel with or lower than the neck, the side of the injection uppermost. A spot is selected 4 to 5 cm lateral to the midline opposite the seventh cervical spinous process (for the injection above the first rib). A wheel is made and the muscular aponeurosis is anesthetized. The 9 cm (1 inch) needle is introduced at an angle of 25 to 30 degrees with the plane of the back and somewhat caudad. It may strike at a depth of 3 to 4 cm (1½ inches), the first rib or the transverse process of the seventh cervical vertebra. In such a case it must be redirected higher (more cephalad) or lower (caudad) as the case may be and at a point perhaps 2 cm (¾ inch) deeper than the rib should strike the side of the vertebral body. The needle must then be directed in a slightly more lateral direction so that it scrapes by the vertebral body. In any case it must pass within about 2 mm (say ⅛ inch) of the body lest the point enter the pleural cavity. Its point is passed about 1 cm (¾ inch) past its last contact with the vertebra. Suction on the needle must always be made to exclude bleeding or entry into pleura or lung. On injecting 10 cc of procaine solution vasodilatation should be rapid and Horner's syndrome is to be expected. Should procaine be injected into the lung the patient tastes it (salty flavor) very quickly.

—Ed.] However, if the clot is in the iliofemoral segment and especially if it is more than a few days old division of the femoral vein with aspiration of the proximal segment is of doubtful value. The percentage

in thrombi originating from the pelvis or extending high into the external iliac vein

* Burns, Shock, Wound Healing and Vascular Injuries, Military Surgical Manual V, National Research Council. W B Saunders Co., Philadelphia.

except possibly elevation and splitting of the diaphragm. In milder forms the patient complains of sudden choking, dizziness and some dyspnea which however is fleeting or he may complain of upper abdominal cramps resembling those of pylorospasm or acute cholecystitis.

Gastrointestinal tract.² Morphine and digitalis having vagal effects facilitate these reflexes. Epinephrine may lead to pulmonary edema in the presence of hypertension in the pulmonary artery proximal to the obstruction. Atropine combined with papaverine blocks the reflexes and releases spasm of smooth

Fig. 97—Electrocardiograms of a woman aged 33 with pulmonary embolism ten days after cholecystectomy. One day after severe massive pulmonary embolism: a) sinus tachycardia, T₁ low, T₂ and T₄ inverted, deep Q₁, QRS complex low in leads 1, 2 and 3. Two days after embolism: sinus tachycardia, T₁ and T₂ low, T₃ and T₄ inverted, deep Q₁. Eight days after embolism: sinus tachycardia, T₂ and T₄ inverted, marked improvement as compared with first tracing. Sixteen days after embolism: sinus tachycardia, T₁ and T₂ low, T₃ and T₄ inverted, deep Q₁, T₁ and T₄ depressed as compared with previous tracing. The ST segment in lead 1 is more nearly normal. There is less depression of T₂ and T₄. Twenty-three days after first, six days after second embolism: As compared with previous tracing, T waves are more depressed in all leads. Thirty-two days after first, fifteen days after second embolism: ST segment slightly elevated, T₄ inverted, deep Q₁, as compared with previous tracing. T₁, T₂ and T₃ more nearly normal, T₄ still inverted, marked improvement.*

The mechanism of these widely spread and inconstant symptoms is shown in the diagram (Fig. 98). Following lodgment of a small embolus, radiation of autonomic reflexes occurs which are predominantly vagal; there is vagal inhibition of the heart and coronary constriction; there is spasm of the unobstructed part of the pulmonary arterial tree, of the bronchi and of the upper gas

muscle of the bronchi and the gastrointestinal tract. Both atropine and papaverine are potent coronary vasodilators; papaverine inhibits ventricular fibrillation; the ultimate cause of death in many such cases.

Treatment.—The treatment is obvious at the earliest suspicion of a pulmonary embolus; oxygen preferably 95 per cent must

* de Takats, JAMA 1931.

be given by mask Atropine $\frac{1}{15}$ to $\frac{1}{60}$ gr and papaverine $\frac{1}{2}$ gr are given intravenously and may be repeated every hour until the patient's condition improves. In

FIG. 98.—The afferent impulses travel mainly in the vagus nerve and radiate back to the lung as bronchoconstrictor and bronchodilatory fibers. They may also stimulate the coronary arteries, produce vagal inhibition of the heart and depress the blood pressure. They can radiate to the upper part of the gastrointestinal tract and produce colic, increased peristalsis and reverse peristalsis. The plug may produce stimulation of the sympathetic vasoconstrictors or a more general sympathetic stimulation through the dilatation of the right heart (Bainbridge reflex). The hypertension in the right heart and in the pulmonary artery seems to be the main stimulus for these widespread reflexes, although the rise in intrapulmonary pressure, the congested lung and the irritated pleura all have been shown to act as reflexogenic factors.*

In case of death autopsy will reveal a small peripheral embolus and no acute coronary occlusion. Often however a myocardial infarct may be found due to acute coronary

insufficiency in a previously damaged heart.⁴

Since a small embolus after the patient's survival of the initial attack may grow by apposition and may obstruct larger areas the use of anticoagulants is definitely indicated. Such treatment is equally beneficial against the primary source of the embolus which is sometimes obvious, sometimes suspected and often unknown. If the source of the embolus is in the calf muscles, division of the femoral vein distal to the profunda is indicated. If the thrombus is higher than that proximal division of the vein only seems indicated in the case of septic emboli. Pulmonary embolectomy if considered at all is reasonable only in the slowly fatal cases with increasing right heart failure.⁶

Sequelae.—If the patient survives the initial attack there may develop a hemorrhagic infarct, pleurisy with effusion, atelectasis, pneumonia or even gangrene. For this reason roentgenograms are of little diagnostic aid since the typical wedge-shaped infarct is hardly ever encountered. Prophylactic use of moderate doses (60 to 90 gr) of sulfadiazine in all cases of pulmonary infarction is logical. Pleurisy with effusion or so-called virus pneumonia always should be regarded with suspicion when evidence of peripheral venous thrombosis is present.

EMBOLISM OF PERIPHERAL ARTERIES

The main source of emboli in the peripheral arteries is in the left heart and less frequently in the aorta; the pulmonary veins need hardly be considered. Mitral stenosis and myocardial thrombi are the two most frequent heart lesions. A group of arterial thromboses occurs after operations, infectious diseases or artificially produced chill and may easily be thrust farther into the periphery of the arterial tree. Arterioelectric plaques of the aorta may be the source of peripheral emboli.

Acute arterial occlusion produces motor and sensory paralysis. The skin is pale and clammy and the pulses are absent. Pain is not an early symptom and may be absent for many hours if the patient is immobilized. Should secondary venous thrombosis occur the limb becomes mottled or cyanotic.

The differential diagnosis between arterial

thrombosis and embolism is important from the standpoint of prognosis and therapy. Thrombosis usually comes on gradually. There is a history of previous symptoms due to arterial disease. On the other hand the history and presence of an organic heart lesion, the presence of some systemic infection or a postoperative status in a patient with cardiovascular disease or vasomotor collapse and the sudden onset of signs and symptoms of acute ischemia are unmistakably characteristic of arterial emboli. Occasionally differentiation between thrombosis and embolism is impossible.

The embolus usually becomes lodged at the major bifurcations of the peripheral arteries where the lumen of the vessel suddenly decreases. In 335 cases the incidence of emboli in the various locations was as follows: 1 subclavian 2 axillary 18 brachial 40 radial 2 ulnar 1 aorta 34 common iliac 50 external iliac 10 common femoral 131 superficial femoral 11, popliteal 33 and posterior tibial 3.

Prognosis—This will depend on the cardiovascular status of the patient on the extent of the collateral circulation at the obstructed level and on early diagnosis and early treatment. It must be remembered that not infrequently a second or third embolism of the extremities or of the cerebral, coronary or mesenteric vessels will cause the patient's death.

Treatment—Treatment of peripheral arterial embolism requires first accurate localization of the embolus. Knowledge of major arterial bifurcations, absence of pulses below and increased pulsations above the obstruction occasionally the actual palpation of the clot or visualization by intra-arterial injection of opaque substances such as neostiodan are helpful. If the patient is seen within the first six to ten hours after the sudden onset of symptoms an attempt to extract the clot is warranted.

Successful embolectomy requires training in and equipment for the technique of arterial sutures. It is important to remember that only a few hours are required before secondary arterial thrombi may occlude the peripheral branches of the artery thus nullifying the effect of relieving the original obstruction. Also the vessel wall tends to embolize so fast that a secondary thrombus

can occur at the site of the removed embolus. Nevertheless in a collective review of 296 cases 47 per cent of the embolectomies performed on the upper extremities 40 per cent on the lower extremities and 91 per cent in the pelvis alone in the first ten hours were successful.

Statistics collected in Sweden showed that of 382 patients on whom embolectomy was performed 60 per cent died 20 per cent required amputation and 20 per cent left the hospital with a restored circulation. Follow up studies showed that of this group three fourths were alive one year half of them three years and eighth of them ten years after the operation.⁴

Recently three important conservative measures have been advocated to prevent gangrene following peripheral arterial embolism. One is the intravenous use of papaverine in doses of from $\frac{1}{4}$ to $\frac{1}{2}$ gram three times a day, the other is institution of intermittent venous hyperemia. These measures used separately or preferably in combination with each other seem to act by relieving the massive collateral spasm which occurs when an artery is obstructed.⁵ Paravertebral block of the sympathetics is the most efficient measure for enlarging the vascular bed to its capacity. If it fails to restore the temperature and the color of the limb embolectomy, the method of choice in the first ten hours. Whatever type of treatment is chosen anticoagulants are urgently needed in order to prevent the occurrence of thrombosis distal to the embolus and the plugging of important collateral arteries.

FAT EMBOLISM

Mobilization of the body fat from certain depots such as the bone marrow or subcutaneous fat through the peripheral veins into the pulmonary circulation is the most frequent type of embolism. The chief source of fat embolism is the bone marrow. The following factors are necessary for the occurrence of fat embolism: (1) severe trauma which injures the fatty tissue and ruptures veins, (2) gapping of these veins which readily occurs in the veins surrounded by rigid bone and (3) a negative sucking action in the veins or a positive pressure from without supplied by a grow-

ing hematoma or inflammatory edema within the bony canal

All these factors are present following fracture of long bones. In addition, marrow fat has a lower melting point than tissue fat and therefore more readily liquefies. Outside of fractures, fat embolism has been known to occur in acute osteomyelitis or following injuries to other fatty depots of the body, but such cases are extremely rare.

The fat carried from the site of injury through the peripheral veins to the right heart is capable of passing through the capillaries of the lung and thus enters the general circulation. This depends on the

Of 112 fatal cases of fat embolism, 104 were due to fractures.¹¹ In 50 per cent of the cases, multiple fractures were present. The lung may show edema or punctate hemorrhages but the diagnosis is sometimes only made with the microscope (Fig 99). The accompanying shock of an injury with a resulting fall in blood pressure may make otherwise insignificant amounts of fat in the pulmonary capillaries the cause of death.

Symptomatology.—Clinical symptoms of dyspnea, cyanosis, cough and restlessness may occur several hours or days after the injury. The sputum may contain blood sediment droplets of fat. Moist râles and signs

Fig 99.—Fat embolism in a sixty year old man who suffered fractures of both scapulae and seven ribs on each side. He was very restless and dyspneic on admission. Thirty-one hours after the injury, he suddenly expired. Photomicrograph shows fat droplets stained with osmium in a small artery at a bifurcation. (Courtesy of Dr. Edwin Hirsch, Pathologist to St. Luke's Hospital, Chicago.)

amount of the mobilized fat and on the blood pressure in the pulmonary artery. Several days sometimes elapsing before the fat passes through the pulmonary circulation. It need not necessarily produce symptoms and simply appears in the urine, or it may produce embolic occlusion and infarcts in any organ of which the brain, heart, kidney and skin are most important. It has been emphasized that fat floats on the surface of the urine and may not be detected unless the last few cubic centimeters of urine is expressed. In the presence of fat, a drop of urine heated on a wire loop sizzles.¹⁰

of pulmonary edema develop only after the right heart begins to fail. The pulse then becomes rapid, the blood pressure falls and cyanosis and later unconsciousness develop. The average duration of life in fatal cases of fat embolism is from two to three days. There may be, however, regression of symptoms to complete recovery, no matter how serious the initial symptoms.

The clinical symptoms of fat embolism in the systemic circulation are mainly cerebral and cardiac. There is usually an interval of several days between the manifestation of pulmonary and of cerebral symptoms or the patient is unconscious and the pulmon-

ary symptoms are not in evidence. The cerebral symptoms consist of a stage of somnolence, loss of memory or disorientation followed by a comatose stage with loss of reflexes, incontinence of stool and urine and finally death. In non fatal cases which not infrequently occur following severe fractures only the first stage of somnolence or disorientation is seen. There may be punctate hemorrhages in the retina or in the skin.

Diagnosis—It is most important to differentiate between cerebral fat embolism and intracranial hemorrhage. In the former there are no signs of increased intracranial pressure, the pupils are usually normal and the spinal fluid is free from blood. There is a free interval however between trauma and cerebral symptoms which of course is present in both conditions.

Prophylaxis—Proper splinting and avoidance of unnecessary transportation without complete immobilization of fractures are important. Anesthetics that increase or predispose to shock such as ether or morphine should be avoided. In osteotomies the saw should be used in preference to the chisel. Major orthopedic operations on the extremities are best done under a rubber constrictor.

Treatment—Adrenalin raises the blood pressure and aids the right heart to dislodge some of the fat from the capillaries of the lung. Ephedrine may be given for the same purpose. It has also been proposed to open and then ligate the main vein draining the injured bone should symptoms of fat embolism recur. No emulsifying agent given intravenously has been found to protect the experimental animal from fatal fat embolism.

AIR EMBOLISM

The entrance of air into the vascular system requires gaping of the injured vein and a marked negative sucking action toward the heart. These factors are present at the large veins of the neck and root of the arm (internal and external jugular subclavian and axillary veins) that are fixed by fascial coverings and cannot readily collapse. The placental veins following childbirth are another source of air embolism. The emboli may contain amniotic fluid.¹ The pulmonary veins when surrounded by scar tissue

that prevents collapse are particularly predisposed to permit entrance and transport of air. The anterior bronchial veins empty into the pulmonary veins and from here into the left heart; the posterior bronchial veins empty through the azygos or the intercostal trunks into the right heart.

The capillaries of the lung are not permeable to air as they are to fat but through in open foramen vile air may pass from the right heart to the left. Should air however reach the arterial tree it can pass through the capillary bed into the venous system. This difference between the pulmonary and peripheral capillary beds may be best explained by the much greater pressure in the peripheral arterial circulation.

When air enters the right heart it is pressed in the shape of foam or large bubbles into the pulmonary artery; death occurs through asphyxia just as in thromboembolism should a large bubble completely occlude the artery or it may plug the smaller branches and it is usually assumed that when two thirds of the vascular bed is occluded asphyxia begins.

The surgical procedures that are most apt to be followed by the occurrence of air embolism are thyroidectomy, radical breast amputation, puncture of paranasal sinuses, injections of air into the bladder or into joints or tubal insufflation. Childbirth or operations on the pregnant uterus may produce an air embolism. Pleural puncture, pneumothorax or operations on the lung itself may produce an embolism of the peripheral arteries. The danger of air embolism from intravenous drip or injection treatment must be minimal as 5 to 10 cc. of air has been injected rapidly in man without producing clinical symptoms.¹²

Symptomatology—In the case of venous air embolism the characteristic hissing sound is heard almost immediately followed by a peculiar churning in the heart. The intensity of this second sound varies from one which is heard at considerable distance from the patient to one which is barely audible with the stethoscope. This is followed by dyspnea, cyanosis, a small rapid pulse and the feeling of tightness in the chest all of which may quickly disappear or progress to unconsciousness and death. As in thromboembolism death may be in

stantaneous or may occur after several hours. In arterial embolism sudden pallor is characteristic segments of the tongue or of the retina may become anemic. Blindness, dizziness and tonic and clonic convulsions signify the cerebral insult.

Diagnosis—The diagnosis is readily made if the hissing or churning sound of air is obvious. If this is not the case vasomotor collapse or thromboembolism may give an identical picture. In gynecological or obstetrical cases large pockets of air may form between the uterus and the placenta or in the peritoneum following rupture of the uterus and may remain silent for hours or days before they are suddenly sucked up into the venous circulation. In cases of arterial embolism the visualization of air bubbles in the retina—should there be time and opportunity for ophthalmoscopic examination—makes the diagnosis certain. Petechial hemorrhages in the skin are also characteristic.

Prophylaxis and Treatment—Large veins in the neck should be handled with caution. Veins should preferably be ligated before section. Frequent sponging with moist compresses may diminish the danger of an air embolism. If a vein is opened and bubbles become visible at the site of injury, a finger or moist sponge should immediately occlude the opening. Once the air has entered the right heart nothing can prevent the further course of events. A horizontal position may aid to keep the air bubble in the right ventricle, whereas a change to a semisitting position has been known to kill the patient instantly. [Bohn¹ reports a case of nearly fatal air embolism with misuse of a positive pressure apparatus for intravenous fluid administration. The patient recovered after aspiration of about 50 cc of blood stained froth from the left external jugular vein.—Ed.]

The prophylaxis and treatment of air embolism from the pulmonary veins is naturally different. Great care must be exerted in establishing an artificial pneumothorax in that the needle is in the free pleural cavity. In cutting or cauterizing lung tissue the use of positive pressure is advisable. The

patient's head should always be lowered so that in case an embolism occurs the air bubbles will not ascend into the cerebral vessels. Plugging of cerebral or coronary vessels with air is rapidly fatal. In both venous and arterial embolism prophylaxis is most important. The administration of 100 per cent oxygen may save life or minimize permanent damage by absorbing the nitrogen bubbles from the vascular tree.¹⁴

XI. THE LYMPHATIC SYSTEM

DISEASES OF THE LYMPHATIC SYSTEM

The lymphatic system maintains the front line of defense against the invasion of the body by infection. As a consequence it is of peculiar surgical significance. Neglected in the past for the more conspicuous arterial and venous systems it has come to assume an importance commensurate with that of the two other great circulations. With the advent of ideas concerning cellular immunity the protective function of the flow of lymph through the lymph nodes has become more clear.

Absorption was solely a function of the lymphatic vessel. This was in the eighteenth century. The utilization by the body of water and minerals—a major part of the lymph problem—is constantly concerned in the modern management of surgical disease.

ANATOMY AND PHYSIOLOGY

The lymphatic system consists of the *lymphatic vessels* and the *lymphoid organs*. The endothelium lined vessels originate blindly throughout the body (Fig. 100 A) with the exception of the central nervous system, muscle bundles and the substance of the

Fig. 100—The structural basis of the lymphatic system (simplified diagram). A The irregular blind-ending lymph capillaries. B The reticular network. C The afferent tubular lymphatics containing valves. D The lymph node present above the lymph sinuses and below the afferent lymphatics. E The efferent lymph vessels showing above the arrow numerous valves.

Transport of the major portion of the fat absorbed from the intestine is another function of the lymphatic system. While this is perhaps of greater significance to metabolism and nutrition nevertheless it has as will be seen certain surgical implications. The mesenteric lymphatics, the arteries containing milk of *Trasistratus* were originally recognized in 1692 by the Italian anatomist Aselli because of this property.

The formation, flow and absorption of lymph are fundamental physiologic problems. Nevertheless they and particularly their solutions have a direct bearing on surgical progress. John Hunter, British surgeon, anatomist, even maintained that the

spleen. This closed thin-walled network collects the lymph from the surrounding tissues. The *lymphatic capillaries* gradually unite to form large vessels (Fig. 100 C) which contain numerous valves. These conduct the lymph to the *lymph nodes* where it flows through the *lymph sinuses* (Fig. 100 D). The efferent vessels join to establish still larger trunks (Fig. 101) which empty the lymph into the large veins at the base of the neck. Other *lymphatic anastomoses* have been noted. The lymphatic system thus differs from the continuous closed blood vascular system in two significant respects: (1) It returns in a roundabout way a part of the tissue fluid

to the general circulation in the form of lymph and (2) this lymph passes through numerous lymph nodes interspaced along its course

parts involved. As a consequence it is of value to review at greater length the anatomy and physiology of the lymphatic system.

Lymph is the fluid which flows through the lymphatic vessels. It is derived from the tissue fluids. These originate from two chief sources. The greater part arises from the blood capillaries into the tissue spaces. This part is essentially a modified blood plasma. Another portion originates as a result of the metabolic processes within the tissue cells. Since tissue cells differ in structure and in function the composition of this portion of the tissue fluid varies. The mechanism of formation of the tissue fluid after extensive researches and much controversy is not yet clear. Likewise the process of its absorption into the lymphatics to form the lymph is an unsolved fundamental problem.

An analysis of lymph reveals that there are but few essential differences between it and blood plasma. It has less protein. Since it contains less fibrinogen than the blood plasma it coagulates more slowly. On the other hand under inflammatory conditions it becomes rich in proteins and coagulates more readily. The products of tissue metabolism may render it toxic. Its quantitative composition varies greatly depending on the activity of the part from which it is collected. It is greatly altered under certain pathologic conditions. In certain forms of edema it is poorer in solids.

Chyle is a milky admixture of lymph and emulsified fat formed in the blindly ending lacteals in the centers of the intestinal villi during digestion. During starvation the distensible lacteals are collapsed and the decreased intestinal lymph is then quite similar to other lymph.

Lymphatic vessels are found with certain exceptions some of which have been noted wherever there are blood capillaries. However there also exist throughout the body irregular slit like spaces and cavities within the connective tissues. These *tissue spaces* are not a part of the lymphatic system although they contain a tissue fluid which has often been called lymph. Similar to these tissue spaces but on a larger scale are the *synovial cavities* and the *meningeal spaces*. In this group are also the mesothelium lined

Fig. 101.—Diagram of the lymphatic system (adapted from Cunningham) showing the main vessels. A Brachial nodes. B lateral axillary nodes. C central axillary nodes. D infraclavicular nodes. W subinguinal nodes. X testes. Y penneal and scrotal vessels. Z vessels from lower extremities. 1 right lymphatic duct. 2 superior vena cava. 3 left and right innominate veins. 4 left and right internal jugular veins. 5 left and right subclavian veins. 6 thoracic duct.

An understanding of the nature of lymphatic disease or for that matter of other surgical diseases is based on an adequate concept of the structure and function of the

serous cavities—peritoneal pleural and pericardial and the tunica vaginalis etc. The term lymphatic should be reserved for the endothelium lined channels.

The *lymph capillaries* (Fig 100 A) begin blindly as irregular thin walled tubes. They branch and anastomose freely forming a closed network. This *reticular network* (Fig 100 B) lies close to the smaller blood capillary plexus however deeper from the skin surface. *Tubular lymphatics* (Fig 100 C) emerge from this network and pass to the lymph nodes and beyond. These are beaded in appearance owing to their numerous valves. Smooth muscle is found in their walls. The larger *lymphatic vessels* unite and become progressively thicker walled until they form the thoracic duct (Fig 101 N). The wall of the thoracic duct is similar to that of a great vein with the exception of a thicker more muscular media.

The *lymphoid organs* are intimately connected with the lymphatic vessels. Essentially they consist of a collection of lymphoid cells lying in a mesh-work of reticular fibers. Most important are the *lymph nodes* (lymphoglandulae) commonly known as lymph glands. They 'filter the lymph' which slowly flows through their network of *lymph sinuses* (Fig 100 D). These sinuses closely surround the *lymphoid nodules*.

Substantially all of the lymph passes through one or more lymph nodes on its way to the veins. The significance of this fact in the resistance of the body to infection may be readily demonstrated. Tubercle bacilli injected into the groin of a guinea pig may be recovered in the iliac lymph nodes.

The lymph nodes have other functions. They manufacture lymphocytes principally in the lighter staining germinal centers of the lymphoid nodules (Fig 100 D) where mitoses are frequent. They remove foreign particles for example inhaled soot in the lungs. They form phagocytic cells which consume bacteria. The lymphocytes however, are not phagocytic. It is an open question whether they produce immune bodies.

The flow of chyle may be taken as an example of the pathway followed by lymph in reaching the general circulation. From the lacteals it passes through a reticular network in the intestinal wall. In the regions

where Peyer's patches (noduli aggregati) or solitary nodules are present the chyle flows through a fine meshed network closely surrounding the lymphoid nodules. It leaves through stems at the mesenteric attachment to enter small lymph nodes lying close to the intestine and between the two peritoneal layers of the mesentery. It passes usually through three series of mesenteric lymph nodes of increasing size. The first lie about the origin of the superior mesenteric artery. There are from 100 to 200 mesenteric nodes. The protection thus afforded against infection from the intestine is evident. The vessels connecting the mesenteric lymph nodes contain valves.

Chyle then leaves the mesenteric nodes to flow through the celiac nodes. The efferents from this group of about twenty large retroperitoneal nodes may enter the *cisterna chyli* (Fig 101 P) directly join the left *lumbar trunk* (Fig 101 Q) or form a separate *truncus intestinalis* (Fig 101 O) which empties into the *cisterna*. From there chyle is transported by the thoracic duct to the left subclavian vein (Fig 101). The flow of chyle may be readily demonstrated experimentally.

The flow of lymph from other parts of the body has no characteristic course. In a similar manner it passes through definite groups of lymph nodes on its way to the veins. Since lymph nodes are the site of deposit of malignant metastases and since pathogenic organisms are carried to them, the area drained by any given group is of significance. These facts and instructive diagrams may be found in any standard text book of anatomy.

The Flow of Lymph—The flow of lymph corresponds in part to the more rapid circulation of the venous blood. It becomes of significance in four conditions. (1) It plays a part in maintaining the normal fullness of the tissues. This the *tissue turgor* is also dependent on the blood capillary circulation as well as the state of the tissue fluids. This tissue turgor is notably decreased in infants under certain pathologic conditions. It is obviously increased in lymphoedema. (2) Pathogenic organisms originating in an infected finger in the intestine or in the tonsils are disseminated by the flow of lymph. (3) Malignant cells some destined

to lodge and form distant metastases are carried along by the lymph current (4) Waste products from the tissues and nutrient substances such as chyle are also transported As a consequence certain features of the mechanics of lymph flow may be briefly considered

The *vis a tergo* the propelling force is substantially a difference in pressure between the two ends of the lymphatic system In the lymph capillaries the pressure is increased Where the main trunks open into the great veins of the neck the pressure is low and may even be negative It is difficult to estimate the lymph capillary pressure Actual measurements are not available The actual effect of the tissue fluids and of the tissue turgor on the lymph capillary pressure is not clear The pressure in the adjacent blood capillaries varies up to 92 mm of mercury It seems reasonable to presume that the lymph capillary pressure depends on the pressure within the blood vessels and consequently on the force of the cardiac systole The heart beat thus supplies some of the energy for the slower circulation of the lymph

Necessary factors also play a part Smooth muscle is found in the walls of the tubular lymphatics An unusual amount occurs in the thoracic duct Numerous closely spaced valves exist along the lymphatic vessels and particularly at the entrance of the main trunks into the cervical veins The pumping action of the intestinal villi aids in the propulsion of chyle Muscular activity and the respiratory cycle also play their part

Compared to the venous circulation the flow of lymph is slow Its velocity although variable has been estimated as $\frac{1}{4}$ mm a second The amount of lymph flowing through the thoracic duct as estimated by measuring the amount coming from a lymph fistula is from 50 to 120 cc per hour

THE LYMPHATIC VESSELS

TRAUMA

All wounds open lymphatic vessels The exuding lymph with its contained cells mostly lymphocytes normally contributes to the healing process The serum collecting in a wound is largely lymph This coagulates more slowly than the blood and seals the open ends of the lymphatic network Healing is as a rule prompt and uneventful Subsequent wound secretion is ordinarily absorbed and carried away by the surrounding blood and lymph capillaries If it accumulates excoriation may be necessary

Wounds in the axilla or groin may injure large lymphatic trunks This may occur for example in an extensive biopsy to remove adherent inguinal nodes The discharge of considerable clear fluid *lymphorrhea* ensues The wound may be slow in healing but eventually closes Pressure or cauterization of the wound with silver nitrate may be employed to hasten closure

Injury to the thoracic duct is of major significance It may follow severe trauma However it occurs most frequently during operations at the left base of the neck It has happened for example during the radical excision of tuberculous cervical lymph nodes Since the curved terminal portion of the thoracic duct may extend as high as 5 cm above the manubrium its presence should not be forgotten during extensive dissection in this region

Injury to the thoracic duct is recognized by the presence of chyle in the wound The escapes synchronously with expiration Two courses are then open If possible a lateral anastomosis should be attempted Ligation in this both ends of the duct should be ligated The collateral circulation is adequate (Fig 101 I and J) to return the chyle to the venous circulation Experimentally continuity of the thoracic duct is not necessary to life Following ligation a collateral circulation through the right lymphatic duct develops Other lymphaticovenous anastomoses are even recognizable as described

If the injury is unrecognized it makes it

self known in the following manner. The lower portion of the wound swells. Spontaneously or after the insertion of a hemostat there occurs a gush of milky fluid and a continuous *chylorrhea* then ensues. This is threatening since liters of fluid with contained minerals and fats are thus lost. Rapid emaciation is noted and the general appearance of dehydration and starvation. *Replacement therapy* may be necessary. The resulting *lymph fistula* may be treated by enterization or by firm gauze packing. If these fail dissection and ligation of the injured duct may be necessary. The mortality is reported as being between 5 and 10 per cent. Injury to the right lymphatic duct (Fig 101 I) is not so serious.

LYMPH STASIS

Obstruction to the flow of lymph may involve any of the successive parts of the lymphatic system. For example recurrent *crippels* involving the reticular lymphatics of the skin may result in their partial or complete obliteration. The collection and flow of lymph are thus hindered. The subcutaneous tissues become thickened, sodden and firm and *lymphedema* is the eventual outcome. This consists of three components. The tissue fluids are not properly absorbed. As a consequence they increase and (a) *edema* results. Since the outflow of lymph is impeded the uninvolved lymphatics dilate with fluid and (b) *lymphangectasis* ensues. As the process continues there is added (c) a *cellular reaction* and eventually *fibrosis*.

Lymphedema also results from other causes particularly thrombophlebitis of the axillary, brachial or iliac femoral veins. The inflammation spreads to the surrounding perivascular lymphatics and lymphangitis develops. Some of the lymphatics become sclerosed. This interferes with the return flow of lymph from the extremity. Canceroma of the breast may so invade the axillary lymphatics as actually to interfere with the return flow of lymph from the arm. At first the affected arm is swollen and a pitting edema is present. It then becomes

tight, firm to pressure and uncomfortable. Finer movements of the hands are lost. As the lymphatic block becomes more complete the arm becomes progressively pale, painful and useless. Elephantiasis may subsequently develop.

Phlegmasia alba dolens literally a painful white inflammation is commonly called milk leg. The name was given before the true nature of the process was understood. It is an example of the effect of thrombophlebitis accompanied by blockade of the principal lymphatic trunks. It usually appears a week or ten days after delivery as thrombophlebitis of the iliac femoral vein. The leg becomes swollen and firm. However instead of appearing dusky from the inflammation and venous stasis it is pale, tense and shiny. This effect is doubtless due to the associated lymph stasis. Usually the swelling subsides within two weeks. As a rule the venous circulation is restored in a remarkable manner. The lymph stasis however is slower in receding. A variable resultant edema may persist throughout life owing to some fundamental disturbance of lymph formation and flow.

It may be necessary to differentiate *hereditary edema* from the various lymphedemas. Called also *Milroy's disease* this was described by Milroy in 1892. The principal features are the familial incidence and the circumscribed edema usually of the legs. There is no known cause, local or general. There is no evidence of lymphatic obstruction. The affected limb is painless, pits on pressure and is firmer than in ordinary edema. Acute exacerbations are recognized and have been regarded as the result of a vascular neurosis.

The familial incidence, the absence of all ordinary causes of edema, the continued chronicity and the unimpaired general health are diagnostic marks. *Treatment* consists in early and persistent bandaging together with measures to control the edema. If allowed to go untreated the enlargement may simulate elephantiasis. Lymphangioplasty is of no avail.

Treatment—The treatment of lymphedema depends on the stage at which the disease is encountered. Early mild cases subsequent to the lymphangitis associated with thrombophlebitis in the extremities

respond to rest elevation massage and support by bandaging. It is important in other cases to recognize the underlying cause of the lymph stasis and to manage it properly. In moderately advanced cases the basal metabolism should be determined. Particularly if it is low the administration of desiccated thyroid may prove of value. The results from this are occasionally striking.

Failure of absorption of the edema fluid is essentially a tissue problem since the kidneys are usually normal and function well. As a consequence administration of the newer mercurial diuretics may be considered. These act in part at least on the extrarenal tissues increasing their permeability. As a result of their action the body rids itself in the urine of a striking amount

If the various forms of palliative treatment fail operative treatment may be undertaken. There are two main operative procedures for consideration. *Lymphangioplasty* was introduced by Handley in 1908. Its principle was to furnish a new capillary pathway for the centripetal passage of the obstructed lymph. This was accomplished by inserting long strands of sterile tubular woven silk into the subcutaneous tissues from the wrist or ankle to the axilla or groin. This was done through multiple openings and the free ends were buried before the skin was closed. The silk thus acted as a new lymphatic conduit. Successes have been reported but experimental evidence shows that the beneficial effects are temporary. The threads excite a cellular reaction and

Fig 102—The Kondoleon operation for elephantiasis. A: First: removal of a strip of the edematous skin. B: Water removal of the thickened deep fascia, leaving the muscles. C: closure of the wound.

of salty water. Salty water with ammonium chloride usually depletes greatly the fluid in the waterlogged extremity. The results are best when accompanied by other suitable measures. The data obtained in studying these cases would seem to indicate an increase also in the permeability of the blood capillaries since the outflow of lymph through the lymphatics is mechanically hindered.

In advanced cases *decubitus* may develop and require attention. *Varicose ulcer* may occur in patients with varicose veins and recurrent thrombophlebitis. It improves as the lymphedema receives appropriate treatment. *Vaccine therapy* as well as medication with sulfa drugs has been used to combat the recurring lymphangitis.

In about three weeks fibrosis of the new channel has resulted so that the thread is isolated and surrounded by scar. The thread is later actually disintegrated. Handley frankly states ten years later. In my own hands this plan has not been permanently successful and I am unable to recommend it."

The *Kondoleon operation* (Fig 102) was described by a Greek surgeon in 1912. It has been popularized in England by Rogers and in America by Sistrunk. Its principle is twofold. It physically reduces the size of the enlarged limb by removing large strips of skin and subcutaneous tissue and more important it permits of drainage of the obstructed superficial into the open deep lymphatics. This is effected by removing

widely the scarred and thickened aponeurosis. It will be further considered in the treatment of *elephantiasis*.

THORACIC DUCT OBSTRUCTION

Obstruction to the lymphatic vessels and to the larger lymphatic trunks results in lymph stasis and lymphangectases. The lymph stasis is manifested particularly as edema owing to the inadequate absorption of the tissue fluids. The lymphangectases become evident in an aided manner. On the skin of the involved extremity appear small blebs visible with a hand lens and containing a clear fluid. These are to be noted particularly where there is a dermatitis where the skin has been abraded or in the region of an ulcer. The clear fluid is lymph and in this manner the congestion is partially relieved.

When the thoracic duct is obstructed the same phenomenon ensues. Then however chyle exudes into the peritoneal cavity into the pleural cavity or even into the kidney pelvis or bladder. In this manner occur *chylous ascites*, *chylothorax* and *chyluria*.

A number of conditions have been reported as causing obstruction of the thoracic duct. These may be: (a) enlarged mediastinal lymph nodes, the result of tuberculois or the deposits of carcinoma or of Hodgkin's disease; (b) mediastinal tumors; (c) valvular incompetence with subsequent enlargement of the left atrium and pressure; (d) filarial disease due to the presence of the parent worms within the duct; (e) bilharzias due to the presence of the blood fluke *Bilharzia henatobia* in the duct; (f) stenoses such as occur following the invasion of the duct walls by tuberculosis or carcinoma or its following scarring; (g) cardiac hypertrophy acting by direct pressure; (h) pancreatic neoplasms described by Agnew; (i) intrathoracic goiter reported by Schultze; (j) thrombosis of the left subclavian vein at the usual opening of the thoracic duct; (k) aneurysm of the aortic arch by pinning the duct against the ver-

tebral bodies. (l) malignant disease of the pleura noted by Sahli; (m) surgical ligation as discussed above.

Subsequent to obstruction of the thoracic duct the lymph pressure increases and the lymphatics dilate. A collateral circulation is eventually established through the bronchomediastinal trunk through other thoracic lymphatics or even through capillary anastomoses into the right lymphatic duct. Other lymphaticovenous anastomoses known but not generally recognized may return the obstructed chyle to the veins. Nevertheless leakage occurs and the external chyle may even rupture. Chyle may also pass into the peritoneal cavity from the induced lymphangectases by the mechanism of *diapedesis* according to Sahli.

Chylous ascites may also occur subsequent to direct trauma with rupture of the external chyle, the thoracic duct or any of the larger lymphatic vessels. Carcinomatous metastases filling the mesenteric lymph nodes may so obstruct and dilate the tributary lymphatics as to cause chyle to appear in the peritoneal fluid. *Chylothorax* may likewise ensue after severe injury to the chest.

The treatment is by paracentesis and it may be necessary to repeat this several times. The fundamental cause should be sought and if found should receive due consideration.

Chyle may enter the urine from the kidney pelvis or from the urinary bladder. The simultaneous rupture of blood vessels and of dilated varicose lymphatics has been described. This results in both chyluria and hematuria. The pressure of a tuberculous lymph node on the thoracic duct with the subsequent appearance of chyle in the pelvis of both kidneys has been reported. The lymph stasis involved the lumbar trunks (Fig. 101 Q), the lumbar nodes and their tributaries from the kidney. Havelburg has proved that chyle may escape into the urinary bladder.

ELEPHANTIASIS

Elephantiasis is a late result of chronic persistent lymphatic obstruction. In addition due to increased resistance a recurrent lymphangitis has usually been superimposed on the resultant lymphedema. It in-

febrile attacks similar to those of patients with elephantiasis. Streptococci were cultured from the tissue fluid always at the beginning of an attack.

LYMPHANGITIS

Lymphangitis is an inflammation of the lymphatic vessels. It is due, as a rule, to pathogenic cocci, although various other organisms may act as causal agents. Like other forms of inflammation it may be acute, subacute or chronic. Recurrent varieties are well recognized. Since the lymphatic vessels exist in two forms there are two corresponding varieties of lymphatic inflammation. (1) *Reticular or capillary lymphangitis* may occur anywhere in the skin of the body. (2) *tubular lymphangitis* is most commonly observed in the skin of the extremities. But little is known concerning lymphangitis as it involves the deep lymphatics. It would seem to be more significant than is recognized and consequently, should merit further investigation.

Reticular Lymphangitis—Acute reticular lymphangitis commonly due to streptococcal infection involves the multiple plexiform vessels in which the lymph is collected (Fig. 100 A and B). In its less severe forms it is usually seen in wound infections as a spreading pink to deep red bluish surrounding the area of trauma. Through this portal of entry the invading organisms have entered the lymphatics of the skin and have set up the consequent process of acute inflammation. Varying degrees are recognized, the most severe forms being seen in erysipelas. It is not commonly recognized that a great part of this disease is a progressive inflammatory involvement of the capillary lymphatics of the skin.

The causative pathogenic organisms are usually streptococci. Other bacteria however, such as the staphylococci, the anthrax bacillus or the gonococcus may induce the characteristic changes. An intense hyper-

emia occurs and the area becomes red, tense and swollen. The lymphatic vessels become distended and filled with clotted lymph. Within and about them are many leukocytes. Endothelial desquamation ensues. The inflammation extends in varying degrees to the surrounding tissues. Perilymphangitis or even cellulitis may ensue and in the latter instance suppuration may follow.

The clinical course usually begins with a wound although this may be quite insignificant. It may be superimposed on a chronic eczema or may arise at the margin of a long standing ulcer. The onset is usually acute as the infection invades the networks of vessels. Often there is an early chill and the temperature rises rather abruptly to 102° or 103° F. The pulse rate increases, malaise is noted and general symptoms such as vomiting or headache may ensue. The area is usually quite tender and may be painful. In a day or so depending on the type and severity of the primary infection irregular red streaks may be seen (Figs. 103 and 104) extending from the diffuse red area up the extremity. This is due to the subsequent tubular lymphangitis. The regional lymph nodes become swollen and tender. Along the course of the tubular lymphangitis may appear a diffuse red area, a patchy reticular lymphangitis. The milder infections usually resolve particularly after appropriate treatment. The severer forms may result in necrosis in necrotizing ulcers or in cellulitis with suppuration. If the lymph node barrier proves inadequate the rapidly progressive infection may result in septicemia.

The portal of entry is not always as obvious as in the little finger shown in figure 103. The prick of a contaminated needle has in many cases resulted in rapidly evolving reticular lymphangitis, tubular lymphangitis, acute lymphadenitis, septicaemia and death. This is the popularly termed 'blood poisoning'. However it is the failure of the lymphatic defense which is of primary significance and it might as reasonably be termed 'lymphatic inadequacy'.

Treatment will be discussed later after a consideration of the closely associated tubular lymphangitis.

Tubular Lymphangitis—Acute tubular lymphangitis is an acute inflammation of

volves particularly the legs but may occur in the arms, scrotum, vulva or breasts. There are varying degrees. In well developed instances the parts are truly elephantine. The skin is enormously thickened and thrown into folds and the epidermis often presents numerous warty projections. There is a firm edema of the less involved parts. The dermis is greatly thickened and fibrosed and the subcutaneous fat is excessively increased. It is scarred and its deeper portions are water logged. Near the deep fascia it contains much free watery lymph. The deep fascia is surprisingly thickened its outer surface being rough and papillary and attached to the fibrous trabeculae separating the edematous fat lobules. Its inner surface is smooth and appears normal as do also the underlying muscles.

Various forms of elephantiasis are described. Galen recognized the disease as occurring along the southern Mediterranean coast hence the name of the tropical form *elephantiasis arabum* which is due to *filariasis*. There are several species of the small causative threadworm. The common one *Wuchereria (Filaria) bancrofti* is from 2 to 4 inches in length and about the size of ordinary catgut. The worms are bisexual the males being the smaller. When mature they breed and later the females produce living embryos. These enter the blood stream where they may be found microscopically wriggling among the blood corpuscles. These minute embryos living in the blood are called *Filaria sanguinis hominis*. The adult worms live in the lymphatic system. They are found in the various lymphatic vessels and in the sinuses of the lymph nodes. By obstructing and damaging the lymph channels they set up a variety of pathologic changes. Among the diseases due to filariasis are lymphangitis, lymphadenitis, hydrocele, lymph scrotum, chylous ascites, chylous cysts and elephantiasis.

Filariasis is transmitted by the bite of the mosquito *Culex fatigans*. Other anophelines however may act as the intermediate host. The blood borne embryos leave the stomach and metamorphose within the muscles of the insect carrier. This takes about twelve days (Low). The larvae then migrate to the head and pass out along the bill of the mosquito. They enter the skin through the

puncture wound or may even penetrate the unbroken epidermis. On reaching the lymphatics they complete their development and become adult worms.

Treatment—The treatment of filariasis is essentially prophylaxis since proposed treatments of the established disease are unsatisfactory. Antimony salts have been given intravenously but a prolonged course of the highly toxic drug seems necessary. *Surgical treatment* has been applied to three of the manifestations. *Amputation* of the often huge lymph scrotum has proved satisfactory. In skilled hands it is a safe operation. *Excision* of the boggy mass of inguinal glands is unsatisfactory. This mass may be mistaken for hernia. It contains enormously dilated lymphatics and consequently varies in size and elasticity. For the elephantiasis the *Kondoleon operation* (Fig. 102) has proved of benefit. It removes at least a great part of the unwieldy mass. The establishment of secondary connections between the superficial and the deep lymphatics is of manifest value. This is a challenging and fundamental surgical problem. It is obvious that the main trunks at the axilla or groin should be patent to obtain the best results. Since in filarial elephantiasis the fundamental cause remains the final result is open to question. *Hindley's lymphangioplasty* is of little avail.

Elephantiasis is not always a tropical disease nor is it always filarial. It may be a sequel to any persistent lymphedema and particularly to those complicated by neglect a dirty skin and consequent recurrent visitations of reticular lymphangitis. For example it has followed carcinomaous blockade of the axillary lymphatics, radical breast amputations, extensive tuberculous invasion of the lymphatics of the leg, ring ulcer of the leg and recurrent attacks of erysipelas (reticular lymphangitis). The Kondoleon operation has proved of greater value in certain of these nonfilarial forms and good results are still being reported.

Experimental elephantiasis has been produced in dogs by Hoar, Drinker and Field who injected a 0.5 per cent solution of quinine iodide in emulsion with a suspension of silica dust into the peripheral lymphatics. The injury of the lymphatic vessels and the nodes to which they were tributary. The injury was sufficient to result in fibrosis and gradual obliteration. The dogs manifested frequent recurrent

febrile attacks similar to those of patients with elephantiasis. Streptococci were cultured from the tissue fluid always at the beginning of an attack.

LYMPHANGITIS

Lymphangitis is an inflammation of the lymphatic vessels. It is due, as a rule, to pathogenic cocci, although various other organisms may act as causal agents. Like other forms of inflammation, it may be acute, subacute or chronic. Recurrent varieties are well recognized. Since the lymphatic vessels exist in two forms, there are two corresponding varieties of lymphatic inflammation: (1) *reticular or capillary lymphangitis* may occur anywhere in the skin of the body; (2) *tubular lymphangitis* is most commonly observed in the skin of the extremities. But little is known concerning lymphangitis, as it involves the deep lymphatics. It would seem to be more significant than is recognized and consequently, should merit further investigation.

Reticular Lymphangitis—Acute reticular lymphangitis commonly due to streptococcal infection involves the multiple plexiform vessels in which the lymph is collected (Fig. 100 A and B). In its less severe forms it is usually seen in wound infections as a spreading pink to deep red blush surrounding the area of trauma. Through this portal of entry the invading organisms have entered the lymphatics of the skin and have set up the consequent process of acute inflammation. Varying degrees are recognized, the most severe forms being seen in erysipelas. It is not commonly recognized that a great part of this disease is a progressive inflammatory involvement of the capillary lymphatics of the skin.

The causative pathogenic organisms are usually streptococci. Other bacteria, however, such as the staphylococci, the anthrax bacillus or the gonococcus may induce the characteristic changes. An intense hyper-

emia occurs and the area becomes red, tense and swollen. The lymphatic vessels become distended and filled with clotted lymph. Within and about them are many leukocytes. Endothelial desquamation ensues. The inflammation extends in varying degrees to the surrounding tissues. Perilymphangitis or even cellulitis may ensue and in the latter instance suppuration may follow.

The clinical course usually begins with a wound, although this may be quite insignificant. It may be superimposed on a chronic eczema or may arise at the margin of a long-standing ulcer. The onset is usually acute as the infection invades the networks of vessels. Often there is an early chill and the temperature rises rather abruptly to 102° or 103° F. The pulse rate increases, malaise is noted and general symptoms such as vomiting or headache may ensue. The area is usually quite tender and may be painful. In a day or so depending on the type and severity of the primary infection, irregular red streaks may be seen (Figs. 103 and 104) extending from the diffuse red area up the extremity. This is due to the subsequent *tubular lymphangitis*. The regional lymph nodes become swollen and tender. Along the course of the tubular lymphangitis may appear a diffuse red area, a patchy reticular lymphangitis. The milder infections usually resolve, particularly after appropriate treatment. The severer forms may result in necrosis in *necroting ulcers* or in cellulitis with suppuration. If the lymph node barrier proves inadequate the rapidly progressive infection may result in *septicemia*.

The portal of entry is not always as obvious as in the little finger shown in figure 103. The prick of a contaminated needle has in many cases resulted in rapidly evolving reticular lymphangitis, tubular lymphangitis, acute lymphadenitis, septicemia and death. This is the popularly termed 'blood poisoning'. However, it is the failure of the lymphatic defense which is of primary significance and it might as reasonably be termed lymphatic inadequacy.

Treatment will be discussed later, after a consideration of the closely associated tubular lymphangitis.

Tubular Lymphangitis—Acute tubular lymphangitis is an acute inflammation of

the tubular lymphatic vessels commonly called lymphangitis. It is frequently seen in the dispensary. The patient presents a wound of the hand which has become infected and a blister of the foot which has had improper treatment or an infected ingrowing toe nail (Fig 104). The hand or foot is locally feverish, red and swollen from the infection and the associated capillary lymphangitis. It is often tender. Extending up the arm or leg as the case may be are irregular red streaks due to acute inflammation of the walls of the tubular lymphatics (Figs 103 and 104). The regional lymph nodes are swollen and tender.

The *pathogenic organisms* are frequently streptococci. Others however may set up the initiating wound infection with its surrounding reticular lymphangitis. The invaded tubular lymphatics are surrounded by a region of hyperemia. Exudation occurs and the vessels become filled with coagulated lymph, desquamated endothelial cells and leukocytes. Progress along the lymphatic trunks is variable in some cases being quite rapid. It may extend from the finger to the armpit in from twelve to twenty-four hours depending on the type and severity of the initial infection.

The *clinical manifestations* are those of varying degrees of infection with the superimposed red streaks winding up the extremity. This streaking is variable. It usually extends through the first defense nodes but may go around them. It is ordinarily seen to end in the nodes of the axilla or groin. However in some instances it doubtless involves the deeper and invisible vessels extending centrally from the axillary or inguinal nodes which are enlarged, palpable and tender.

The majority of the infections subside rapidly under adequate treatment. Often in four or five days after the onset no residual evidence is seen. On the other hand certain infections are rapidly and progressively fatal even within forty-eight hours after the initial infection. This tragic outcome may be due to the virulence of the infecting streptococcus, the lowered resistance of the patient, the inadequacy of the lymphatic defense barrier or even to injudicious treatment. The fatal result in these cases is due to *septicemia* as may be shown by blood cultures. Further evidence is later found in

the microscopic demonstration of widely disseminated areas of infection.

In other cases local abscesses may form along the tubular lymphatics. The perilymphangitis may extend and diffuse cellulitis sometimes develops which may suppurate. Infection of the hand with lymphangitis and its sequelae may lead to a series of disabling complications unless properly managed.

The *treatment of lymphangitis* comprises prophylaxis, management of the acute infection and recognition of and attention to the complications. Prevention is perhaps best accomplished by rigid surgical care of wounds particularly those of the hands and feet. Where streptococci are known to be present this attention should be scrupulous. Wounds of the hands of manual laborers should receive early and judicious treatment. The skin of the extremity with lymphedema or elephantiasis should be kept clean to prevent recurring attacks of reticular lymphangitis.

The *usual management* of the acute infection is by the institution of rest and the application of hot moist dressings. Use of sulfur drugs is of particular value in those forms due to streptococci. Their effects are sometimes striking. Rest local and general is obviously of value. Hospitalization with the institution of complete bed rest and care often rapidly terminates a severe infection. In case of tubular lymphangitis of the extremities the dressings should envelop the entire arm or leg and cover the axilla or groin. Since local dehydration seems of value the dressings may be kept moist with a saturated solution of magnesium sulfate or with mixtures containing glycerin. Antiseptic solutions have no particular value and may even prove harmful. As the infection subsides the magnesium sulfate solution may be replaced by boric acid or salt solution.

If an abscess develops in the initial wound it should be opened and drained but this is not ordinarily necessary. The septic hand requires special and skilled care. When cellulitis with definite suppuration occurs it should be drained. Incision of the acute tubular lymphangitis should never be done owing to the danger of disseminating the infection. Local abscesses and abscesses within

the regional glands may require incision and drainage. Hilton's method should be employed. The general condition of the patient is aided by an increased fluid intake. If fluids are not readily tolerated by mouth they are best administered by hypodermoclyses of Ringer's solution.

Chronic Lymphangitis—Chronic lymphangitis may follow an acute attack which has not received adequate treatment. It may be maintained in the lymphatics peripheral to a blocking subsequent to previous acute lymphangitis. A recurrent form manifesting itself as periodic attacks of reticular lymphangitis frequently occurs in the skin of extremities with lymphedema or elephantiasis. A specific portal of entry is difficult to determine. The lymph stasis present and an unclean skin are predisposing factors. This form has previously been described. The more common forms of chronic lymphangitis are cancerous, tuberculous, syphilitic and filarial. The sporotrichotic variety is rare. One of the principal effects is an interference with the normal flow of lymph from the involved part due to the progressive thickening, fibrosis and eventual blocking of the lymphatic vessels. The usual results of this have been previously considered.

Tuberculous lymphangitis is rare. With out much doubt the tubercle bacillus is carried about the body and particularly to the lymph nodes by means of the lymphatic vessels, yet the vessels themselves are seldom involved. This would argue for the effectiveness of the lymphatic endothelium.

Occasionally it is seen in the hand or arm as a sequel to a primary focus in the hand. This source of continued infection, the *anatomical tubercle*, may give rise to ascending tuberculous lymphangitis. The lymphatics become thickened and nodular and are palpable. They may become cord like. The nodules are at first firm and solid. Later they soften, form abscesses and break down forming ulcers. The epitrochlear and the axillary glands are invaded. A similar condition occurs in the mesenteric lymphatics and in the mesenteric lymph nodes from intestinal tuberculosis.

The treatment is general and local. The initial lesion should be excised if possible to remove the source of the infection. It may be necessary to curette or even excise

the broken down areas along the course of the lymphatic vessels. The involved lymph nodes may require excision if other measures fail. X-ray therapy is of value.

Sporotrichosis, a rare mycotic disease due to infection with the various species of the *Sporotrichum* presents an unusual form of chronic lymphangitis. (See section on Sporotrichosis.)

Chronic non granulomatous lymphangitis has been described. It is difficult to regard this as a clinical entity. It is not easy to distinguish it from the tuberculous form. However, no specific causative organism has been found. It behaves much as tuberculous lymphangitis, although the tubercle bacillus is not demonstrable. Treatment is directed at the initial lesion and at the enlarged regional lymph nodes which should be excised. The lymphangitis needs no other treatment.

Syphilitic lymphangitis is occasionally seen on the dorsum of the penis subsequent to the primary infection. The lymphatic vessels become firm, cord like and readily palpable. There may be an accompanying lymphedema of the foreskin. The treatment consists of an attack on the causative disease.

Cancerous lymphangitis is an obliterating form due to the plugging of the lymphatics with metastasizing malignant cells. There may be demonstrated microscopically, a surrounding inflammatory reaction and fibrosis.

Filarial lymphangitis, one of the many effects of the invasion of the body by *Wuchereria (Filaria) bancrofti* has been discussed in a preceding section.

LYMPHANGIECTASIS

Lymphangiectases or varicose lymphatics are dilations of lymphatic vessels. They are analogous to hemangiectases which occur in the peripheral blood vessels and contain lymph instead of blood. *Congenital forms* are recognized and result from some disturbance of the normal development of the primitive lymphatic plexus. However, they are most commonly encountered as one of the sequelae of lymph stasis and have been discussed under that heading.

Lymphangiectases may be demonstrated in the mesenteric lymphatics subsequent to extensive invasion and replacement of the

mesenteric and celiac lymph nodes by metastatic carcinoma. When the abdomen is opened the distended lymphatics are sometimes quite evident under the serosa of the intestine. The beaded thin walled vessels are readily demonstrable in the mesenteries and there is often an associated chylous ascites.

Treatment consists principally in considering the cause of the lymph stasis. In local forms not due to obstruction excision may be considered. For these however radium is of particular value.

The transition from lymphangiectases to true tumors of the lymphatic vessels is gradual there being no sharp dividing line. As a consequence considerable controversy has arisen with resultant confusion in the terminology.

LYMPHANGIOMA

Lymphangiomas are true tumors of the lymphatic vessels. They may result from increased proliferation of the vessels to form a palpable snarl or proliferative changes may occur in their walls resulting in tumor formation. Cavernous dilations are occasionally seen without evidence of previous obstruction. The endothelium which lines the vessels may give rise to endotheliomas. They may be congenital or acquired. They will be considered in four groups: *simple cavernous cystic and endotheliomatous*.

The lymphatic nevus is the simplest lymphangioma. It is usually seen in the skin although it occurs elsewhere. It may be colorless or faintly pink and barely palpable or slightly elevated. It is difficult to distinguish it on a rigid pathologic basis from a lymphangiectasis. Criteria which have been used are the evidence of proliferative changes, the connections with the surrounding lymphatic vessels and the evidence of a causal lymph stasis.

The hypertrophic form *lymphangioma hypertrophicum* is more definitely a tumor. It is usually congenital and, as a rule, is located in the skin. It may be flattened, protuberant or even papillary. It is definitely palpable. Although usually symptomless, rupture of the superficial vessels results in *lymphorrhea*. Microscopically the vessel walls are thickened, the endothelium is tall and the lumina are small. The proliferating ves-

sels are surrounded by fibrous connective tissue.

Treatment—Radium is of definite value in the treatment of the simpler forms of lymphangioma. If it is unsuccessful or in the papillary forms excision may be indicated.

Cavernous lymphangioma forms a definite tumor on the head or neck, about the genitalia or in the mesentery. It may be quite large. The lymphatic vessels lose their usual tubular form and become greatly dilated and saccular. The tumor is usually multilocular and the cavities are irregular. Their shape depends on the varying pressure of the surrounding structures. Aspiration yields lymph. The endothelial lining of the cavities is sometimes thickened. In other instances it is lacking in places owing to pressure, cyst formation and distention. Between the sacculations the connective tissue septa contain lymphocytes, elastic fibers and often smooth muscle.

Etiology—The etiology is obscure. The form occurring in the neck, *true cystic hygroma*, may originate from faulty metamorphosis of the primitive cervical lymph sacs. A developmental origin appears most likely although obstruction has been considered.

Disfiguring congenital enlargements of the tongue, face and hands are described. *Macroglossia* is a congenital enlargement of the anterior part of the tongue due to cavernous lymphangioma. The tongue may protrude far from the mouth as in Da Costa's case. It may interfere with breathing or eating. In *macrocheilia* the lips are enlarged by the lymphangioma which may also invade the cheek. *Macrocheiria* results from lymphangioma of the dorsum of the hand. Cavernous lymphangioma also occurs in the mesentery. Since this form contains chyle it has become known as a *chylangioma*.

Treatment—The treatment is by radium or excision. Radium may be used preliminary to surgical removal. Subsequent plastic repair may prove necessary.

The cavities of a lymphangioma may undergo cystic distention in which instance large cystic tumors develop. These occur in the neck as *cystic hygroma* (*hygroma colli cysticum congenitum*). (See section on Cystic Hygroma.)

Endothelioma.—An endothelioma is a

neoplasm arising from the endothelium lining the lymphatic vessels. Even in certain tumors of considerable size it is readily possible to trace the origin of the endothelial cells. On the other hand this is often difficult and for that reason uncertainty and consequent controversy have arisen as to the true nature of these tumors. The microscopic picture is variable. Hence endotheliomas have been regarded by some as forms of carcinoma and by others as sarcomatous. This doubt is reflected in the older terminology in the designation *sarcoma carcinomatodes*. Since endotheliomas also arise from the endothelial lining of the blood vessels the lymphatic form is specifically defined as *lymphangioendothelioma*. One form arises within the perivascular lymphatic vessels. This has been widely designated perithelioma. Though its origin is not likely within the lymphatic endothelium it is difficult to separate it on rigid pathologic criterion from the *hemangioendotheliomas*.

Clinically lymphatic forms of endothelioma occur oftener in the skin occasionally in that of the face as firm discrete slowly growing non-adherent tumors. The overlying skin is uninvolved. They are observed at all ages. They are moderately invasive and later adherence and even ulceration may ensue. Metastases are infrequent. Peritheliomas are found in mixed tumors of the parotid and in tumors of the earrotal body. Lymphangioendothelioma arising from the lining of the sinuses of the lymph node, will be considered later among the tumors of the lymph nodes.

Treatment—Treatment is by excision. The tumors may recur if this is inadequate. The endotheliomas are very susceptible to radiotherapy which is also employed after excision.

THE LYMPH NODES

LYMPHADENITIS

Lymphadenitis is an inflammatory process involving the lymph node. Acute and chronic forms are recognized. The acute forms are more commonly due to infection by pyogenic cocci although various other pathogenic organisms may induce the characteristic features of inflammation. The chronic forms are due to tuberculosis, syphilis, cancerous invasion or to organisms of

low virulence. Since many differing bacteria can cause lymphadenitis there are varying intermediate forms. The lymph nodes may be regionally involved for example subsequent to lymphangitis of the extremities (Figs 103 and 104) or they may be generally affected as in secondary lues.

ACUTE LYMPHADENITIS

Acute lymphadenitis is due in most instances to a lymph-borne infection. Blood-borne infections and those resulting from direct trauma are rare. Among the causative organisms which have been recognized are the streptococci, staphylococci, the Duerer bacillus, *Treponema pallidum* and *Bacillus tularensis*. The portal of entry of the infecting organisms is usually readily demonstrated. It is important to remember that this is the principal feature of the whole disease. This and the consequent lymphangitis have been considered. On the other hand the lymphatic vessels which carry the organisms to the lymph nodes are usually unaffected. This is seen particularly in upper respiratory infections or in acute tonsillitis with subsequent acute cervical lymphadenitis.

The infected nodes become hyperplastic, enlarged and more vascular than normal. At first and throughout moderate infections they remain freely movable and discrete. In severer infections the surrounding connective tissue is involved. The nodes may then subsequently become matted together and adherent. If a virulent infection spreads from the nodes into the adjacent tissues cellulitis may develop. The inflamed nodes have a tendency to suppurate in which instance local abscesses are formed. Resolution usually is complete in the non-suppurative forms. In nodes where the hyperplastic reaction has been severe a subsequent fibrosis may follow. This results in a sclerosed painless node. Suppuration may progress to involve the overlying skin which becomes red and inflamed. In such instances spontaneous rupture may follow. Organisms may remain in the nodes even after resolution, to result eventually in a recurrence.

Symptoms—Clinically the manifestations of acute lymphadenitis and its sequelae vary with the type and virulence of the causative organisms. The disease is more commonly

ity resulted in fairly large nvoid tumors in the submaxillary region

Chancroidal bubo is an acute inguinal lymphadenitis due to the Duerer bacillus. Secondary infection due to pyogenic organisms however is known to occur. It is usually unilateral on the side to which the lymphatics from the primary sore extend. From the first the inguinal nodes are acutely inflamed. Suppuration and *inguinal abscess* are frequent. This usually occurs early in the evolution of the primary disease. It may ensue even after the original chancre has healed.

Deep axillary abscess originates as a suppuration within the axillary lymph nodes under the deep axillary fascia. It is to be differentiated from superficial axillary abscesses which result from infections of the axillary skin and its appendages. The primary infectious lesion is commonly in the hand or more rarely in the breast. If the suppuration is extensive pus fills the axilla and burrows under the pectoral muscles. It may reach the skin through less developed areas of the usually dense axillary fascia. By traveling along the sheath of the axillary vessels it may point at the base of the neck. Diagnosis is based upon the symptoms which include impairment of function of the arm. Fluctuation may be difficult to elicit owing to the tenseness of the axillary fascia.

Subpectoral abscess arises through suppuration of the subclavian lymph nodes. These lie about the upper margin of the pectoralis minor muscle anterior to the costo-clavicular ligament. Infection reaches them from the intermediate axillary nodes directly from the breast or along lymphatics accompanying the cephalic vein. The abscess occupies the apex of the axilla. It may lie in front of or behind the pectoralis minor muscle. It may follow an infection of the hand. Diagnosis is based on the presence of the primary infection and the development of a subsequent tender swelling below the inner part of the middle third of the clavicle. If the pus migrates downward between the two pectoral muscles a swelling may appear at the lateral margin of the pectoralis major muscle. It is to be differentiated from axillary abscess and from arthritis of the shoulder.

Retropharyngeal abscess follows suppuration of the retropharyngeal lymph nodes. It occurs most frequently in infants.

Treatment—The treatment of acute lymphadenitis consists in removing the cause supporting the patient and relieving the local inflammation. If the original portal of entry is promptly recognized and adequately managed the source of the infecting organisms is abolished. The lymph nodes are then better able to cope with the infection in the absence of repeated reinfection. The primary infections are varied and require correspondingly different treatment. In some instances they may be completely removed for example by extricating an abscessed tooth or later by tonsillectomy. In others they may be rapidly cleared by more conservative treatment as by the incision and drainage of an infected hand. Hot moist dressings and rest will usually clear up a chronic suppurating ulcer.

The general resistance of the patient may be supported by rest. Hospital care is of advantage as the rest should be general as well as local. Proper care and attention to the diet should be supplemented by the liberal administration of fluids.

The local lymphadenitis responds best to hot moist dressings. Under the regimen resolution often ensues within a few days. In other cases however suppuration occurs. There is a difference in practice as to the course to be followed in the event of suppuration. Too early incision and drainage may spread the infection. On the other hand too great delay may result in the burrowing of the pus and spread of the infection as well as other complications. If abscess formation is progressing satisfactorily and there are no systemic symptoms incision is best delayed until the suppurating lymph node is converted into a sac of pus and the surrounding induration has practically disappeared. At this time the abscess membrane should be well developed so that the abscess may be explored and loculations cautiously broken. Curettage and all unnecessary trauma should be avoided.

The abscesses are best opened by *Hilton's method* (1863). The skin and superficial fascia alone are incised. By blunt dissection the abscess wall is exposed or if deep indicated by the tip of the blunt hemostat. The

tip is thrust through the abscess wall and opened and the hemostat withdrawn. A soft rubber drain is inserted. This method is of particular value in the neck, axilla and groin where important structures surround the lymph nodes. Deep axillary abscess may require in addition incision of the axillary fascia and tube drainage. A subpectoral abscess should be opened by an incision along the lateral margin of the pectoralis major muscle and drained by a tube extending up between the two pectoral muscles. Retropharyngeal abscess is best opened through the mouth and pharynx by Hilton's method.

CHRONIC LYMPHADENITIS

Chronic lymphadenitis is a disorder which may be the sequel of repeated acute attacks which are the result of prolonged infection by organisms of low virulence or it may be due to syphilis, malignant invasion or tuberculosis. The common form is non-specific and involves the regional nodes draining an area of chronic infection. It is noted for example in children with chronic sculp infections. The nodes in the posterior triangle are enlarged, firm and painless. They may be adherent or even fused. The condition is frequently detected in the groin during a routine physical examination as a sequel to chronic infection or uncleanness of the genitalia. Such nodes, particularly in children, are predisposed to tuberculous infection. It is difficult to distinguish them in some instances from tuberculous nodes. This is best accomplished by biopsy and microscopic examination. *Treatment* consists in eradicating the source of infection and attention to the general health. If the nodes do not disappear after adequate measures, tuberculosis should be suspected.

Non tuberculous granulomatosis has been described as a form of chronic lymphadenitis. It is difficult to regard this as an entity either clinically or from pathologic criteria. Specific causative organisms are lacking. There is a decided resemblance to tuberculosis yet tubercle bacilli are not found. The nodes tend to soften, break down and form

sinuses. The greenish and tenacious pus resembles that found in tuberculous nodes. *Treatment* is by radiotherapy or excision with satisfactory improvement.

Syphilitic Lymphadenitis — Syphilitic lymphadenitis occurs locally in the primary stage generally in the second stage and rarely in the third stage of this disease. Subsequent to the evolution of the primary chancre the regional lymph nodes gradually increase in size forming the *inguinal bubo*. Microscopically, treponemes may be demonstrated and there is resultant lymphoid and endothelial hyperplasia. Fibrosis subsequently ensues and may result in atrophy of the nodes. Clinically the glands are firm and tender. They do not suppurate unless a mixed infection occurs. In that event they may be painful.

During the secondary stage there is general enlargement of the lymph nodes. They are firm, non-adherent and easily palpable. During the early stages certain of the nodes may be tender but as the process advances they become insensitive.

During the third stage gummas may form within the lymph nodes. These are rare with modern diagnosis and antiluetic treatment. Rarely massive gummatous enlargement of the abdominal nodes occurs.

The *treatment* is that of the fundamental disease. The lymph nodes respond rapidly to active antiluetic treatment unless they are sclerosed or secondarily infected.

Cancerous Lymphadenitis — Cancerous lymphadenitis is a chronic form due to the invasion of the lymph nodes by metastatic malignant cells. These produce changes in the nodes by aggregation and multiplication as well as by induced inflammatory changes. The malignant cells are carried in the lymph stream from the primary lesion and usually lodge first in the peripheral sinuses of the convexity of the node. Later the deeper sinuses of the node become filled, the cells proliferate and the normal structure is obliterated. Inflammatory changes due to the reaction of the endothelial reticular and lymphoid cells to the foreign can

cer cells occur. Fibrosis often is evident. The cancer cells pass through the node as may be demonstrated microscopically within the efferent lymphatic vessels at the hilum.

Clinically the primary cancer is usually obvious. In certain patients with cancerous submaxillary lymphadenitis it may prove most difficult to demonstrate. This is due to the fact that a small symptomless carcinoma is hidden in the nasal cavity, the accessory sinuses or the nasopharynx.

The carcinomatous nodes are at first firm, enlarged, discrete and non-adherent. As the proliferating cancer cells invade the capsule of the node it becomes adherent. Adjacent nodes thus fuse to form a large hard mass. As a result of secondary infection and suppuration this mass may form a large abscess requiring evacuation.

Treatment.—The treatment is by radiation and by excision. Both radium and roentgen therapy have been widely employed. Their effects depend on the type of malignancy. Excision is often a matter of judgment depending on the character of the primary lesion as well as the extent of the metastases.

Not all the enlarged regional lymph nodes that receive lymph from a carcinoma are carcinomatous. This is a significant clinical fact. Since the primary carcinoma is often ulcerated and frequently infected, the lymph flowing from it bears numerous organisms. These cause in varying degree an inflammatory process within the nodes. Thus their enlargement may be entirely inflammatory. Such a fortunate occurrence for the patient, however, cannot be trusted.

Tuberculous Lymphadenitis.—Tuberculous lymphadenitis is one of the more common manifestations of tuberculosis which frequently invades the lymphoid tissues. It is often encountered particularly in children and in young persons whose general health is poor because of inadequate food and unsatisfactory living conditions. It involves most frequently the cervical lymph nodes which indicates the significance of the mouth and pharynx as portals of entry. Carious teeth, the tonsillar crypts and the other lymphoid tissues of Waldeyer's ring present favorable regions through which the tubercle bacilli may enter the lymphatic vessels. Thence the organisms are carried

by the lymph stream to the upper cervical lymph nodes and particularly to the superior deep cervical and submaxillary groups. The retropharyngeal nodes may also be invaded. From the nodes in these groups the infection spreads downward along the deep cervical chain. The disease is usually bilateral. In children the bovine type of organism appears to be the usual invader. This means milk-borne infection. In adults in whom the disease is much less frequent the bacilli are usually of the human variety. Tuberculous cervical lymphadenitis formerly known as scrofula is said to be less common than it was fifteen years ago. This may be due to the widespread removal of tonsils and adenoids which are without much doubt important portals of entry and to the more universal custom of pasteurizing milk.

The pathology exhibited by the infected nodes is variable. This is dependent on the virulence of the organisms, the amount of reaction of the endothelial, reticular and lymphoid cells and the previous condition of the nodes following chronic septic infection. In one form the greatly enlarged nodes present little evidence of specific tuberculous infection. Microscopically the appearance is that of hypertrophy and tubercles are rare. These nodes are differentiated with difficulty from the malignant lymphomas. In another form the characteristic tubercles are frequent. Caseation is evident, fibrosis has occurred and the lymphoid and epithelioid cells have increased. The tubercle bacillus may sometimes be demonstrated. Caseation commences as pinpoint foci which enlarge, coalesce and finally convert some of the nodes into a soft caseous mass. The capsule, however, is firm and thickened as a result of fibrosis. Peradenitis results in adherence to the surrounding nodes and to the adjacent structures. The progress of caseation is variable.

The involved nodes are variable in their microscopic picture. They may progress in three ways. First they may manifest preponderant fibrosis and gradually shrink to become firm, adherent nodules. Second, a secondary pyogenic infection may be added with a resultant suppuration and its sequelae. Third, the caseated mass may liquefy and form a tuberculous cold abscess. Cal-

cification may occur in the sclerosing nodes or in those revealing caseation

The abscessed glands become adherent to the overlying skin which becomes involved and ulcerates. Discharge of the tuberculous pus follows with the formation of a sinus. The edges of the ulcer appear unhealthy because of the bluish undermined margin and the pale soft granulation tissue. A thin watery discharge is noted. Certain glands with calcification may cause a more profuse purulent discharge since the calcified masses act as foreign bodies. This clears when the sinus is curetted and the deposits are removed.

Clinically the onset of tuberculous lymphadenitis is rarely recognized as there is no accompanying general symptomatology. The infection is thus insidious. The first evidence to appear is the gradual enlargement of the lymph nodes situated about the angle of the jaw. These may be even 2 cm in diameter easily palpable freely movable and of normal consistency. They are not ordinarily tender and may be found on both sides. At this stage it is most difficult to distinguish them clinically from the enlarged nodes of chronic septic infection. The tonsillar gland lies in this region and there may be chronic tonsillitis. Biopsy with subsequent microscopic investigation is the only certain procedure.

As the disease progresses the adjacent nodes enlarge and swelling is evident. At first they are discrete and not adherent. If the foci of infection are properly treated and the gradual spread subsequently continues it is probable that the infection is tuberculous. Later as fibrosis occurs certain of the nodes become firm. It is difficult to determine caseation. Later abscess formation is recognized by softening and fluctuation.

Axillary tuberculous lymphadenitis is occasionally seen. It follows the evolution of an anatomical tubercle with a resultant ascending lymphangitis. It may ensue as a sequel to tuberculosis of the breast which is rare. The axillary nodes enlarge and fuse and may suppurate.

Mesenteric tuberculous lymphadenitis is commonly known as *tabes mesenterica*. Children frequently present some enlargement of the mesenteric nodes. It is difficult to

estimate the proportion of these that are tuberculous. It is perhaps more common than is recognized. The nodes present the characteristic pathologic changes including calcification. This is readily recognized roentgenologically. It is sometimes found in persons in whom tuberculosis has not been suspected.

Tuberculosis of the peribronchial nodes can likewise be recognized roentgenologically. It is not uncommon as revealed by microscopic studies of necropsy material. Tuberculosis rarely involves the inguinal nodes. It is to be kept in mind however in differentiating inguinal lymphadenopathy.

Treatment—Prophylaxis is important in the treatment of tuberculous lymphadenitis. Since the infection is so frequently bovine an uninfected milk supply is of prime consequence. Attention to the mouth and pharynx the principal portals of entry consists in proper care of the teeth and attention to the tonsils and adenoids. In the incipient disease the same measures hold since in that manner foci of infection may be eliminated. Numerous remedies have been tried for the advancing disease. Controlled heliotherapy using sunlight or the quartz lamp is of value. Bringing the child from an unhygienic home with inadequate food to a well organized institution where good care is provided usually results in improvement. Tuberculin has been extensively used but the results are still uncertain. Roentgen therapy is of value and it will be discussed later.

Early and complete excision of the infected cervical nodes is receiving increased attention. This requires skillful dissection but removes the source of further progress to other nodes. In certain instances it is curative. However unless thoroughly accomplished infected nodes may be left behind. The excision of advanced tuberculous nodes is a laborious procedure. The adhesions encountered call for not only skillful dissection but also an adequate knowledge of the anatomy of the neck. In patients with enlarged nonprogressive nodes it is often accomplished by experienced operators with resultant success. During the late stage curettage of discharging sinuses and of the attached broken down nodes often results in prompt healing.

Röntgen therapy of cervical lymphadenitis is to be considered as a useful form of treatment. The development of modern apparatus and modern technique has simplified the treatment and improved the results. Pfahler has carefully summarized the results obtained by treating 333 patients with both acute and chronic forms of varying degree—193 of these had been diagnosed as tuberculous, 42 per cent had postoperative recurrences. An unusually high percentage of those who returned for investigation showed improvement or were cured. Hospitalization is unnecessary and but few exposures are required. Softening is treated by evacuation through a small incision. Atrophy and telangiectases may now be avoided. Electrothermic destruction of old sinuses and thickened red scars is followed by one or two roentgen exposures.

VENEREAL LYMPHOGRANULOMA

Venereal lymphogranuloma commonly known as *lymphogranuloma inguinale* or the sixth venereal disease involving particularly the lymphatic system of the genital and anorectal regions was originally described by Durand Nicolas and Favre of Lyons in 1903. Stannus' excellent monograph presents a summary of the information available up to 1933. More recent observations have been made by von Haam and his associates of New Orleans.

Venereal lymphogranuloma is a contagious disease that is acquired venereally and is caused by an ultramicroscopic filtrable virus. Experimentally it may be transmitted to certain laboratory animals. It is recognized and differentiated particularly by the nature of the Frei skin reaction. Care should be taken not to confuse it clinically with granuloma inguinale which does not involve the lymphatic system but rather the pudendal skin and subcutaneous tissues and which reveals the characteristic Donovan bodies.

The initial lesion on the genitalia is small and usually herpetiform and may be transitory. Lymphatic dissemination follows with involvement of the regional lymph nodes and

the adjacent connective tissues. There is evidence of an even wider systemic spread (von Haam). Locally there ensues a characteristic subacute inflammatory process which becomes productive and chronic. This usually results in the formation of multiple small foci of suppuration with subsequent tiny fistulas.

The associated constitutional symptoms are variable and are usually noted during the stage of lymphatic invasion. Fever, rigors and sweats occur at anorectal irritation and vomiting. These result in loss of weight, lassitude and prostration.

In men the usual localization in the inguinal nodes gives rise to a characteristic clinical picture termed climatic bubo. With the development of subsequent extensive lymphatic blockage, elephantiasis of the penis and scrotum may follow.

In women there is more frequent involvement of the intrapelvic lymph nodes. As this progresses the syndrome known as ecthyma may ensue characterized by elephantiasis and ulceration about the vulva and in the anorectal region. This may lead to inflammatory stricture of the rectum.

Von Haam has analyzed the principles of treatment. Surgical excision of the mass of infected lymph nodes in the groin may be recommended since beneficial effects have been demonstrated. Abdominoperineal resection with colostomy has been tried for the rectal stricture. Treatment during the late stages is far from satisfactory. Consequently prophylaxis is most important.

TUMORS OF THE LYMPH NODES

Enlargement of the lymph nodes follows proliferative changes occurring within their component tissues. In one group of lymphadenopathies the proliferative changes are induced by infection. This may be readily demonstrated. An example is presented by the adenopathy of chronic septic lymphatic

enitis These nodes exhibit a varied microscopic picture and were the pathogenic organisms lacking would be distinguished in certain instances only with difficulty from certain neoplastic nodes. In a *second group* although the microscopic picture resembles in some respects that of an infectious lymphadenitis, no specific infecting agent has thus far been found. In this group uncertainty consequently exists. Certain features point to malignant disease, others suggest infection. As a result classification on a rigid pathologic basis is difficult principally since the etiology is not clear. The outstanding example of this group is *Hodgkin's disease*, the true nature of which is still a matter of controversy. In the *third group* the cellular multiplication is clearly neoplastic. There is evidence of invasion and of deposits in other structures. The best example is found in *lymphosarcoma*.

Lymphoma, a term used to designate a proliferative tumor of lymphoid tissue, may be applied to lymph node tumors. It is however non-specific and should be qualified. The group of lymph node tumors which are not clearly due to infection should be considered as malignant. They grow with out restraint, deposits occur, and treatment is ineffective. They have consequently a high mortality rate. Future investigation may show that they are due to some obscure disease of the blood-forming organs, or an infectious basis may be unquestionably established. Nevertheless for the present it is expedient to group them together as the *malignant lymphomas*.

HODGKIN'S DISEASE

Hodgkin's disease was described as a clinical syndrome in 1832. Its name was given it by Wills in 1866. One or possibly two, of the original seven cases which Hodgkin reported are now regarded as valid examples of the present conception of the disease. Two appear to be tuberculous; three would seem to correspond to forms of leukemia. It has been the task of subsequent investigations to separate the differing members of the original group. The leukemias were differentiated in 1846 by Virchow on the basis of the great increase in the leukocytes. Cohnheim separated the aleukemic form in 1866, designating it *pseudoleukemia*. The clinical picture was similar to that of leukemia, however the characteristic blood findings were lacking. The relation to tuberculous was reintroduced by Sternberg in 1898, who regarded the inflammatory form as due to the tubercle bacillus. In 1902 Dorothy Reed characterized the cellular appearances of the in-

volved nodes and set forth a reasonable basis for the identification of the disease.

One of the results of the uncertainty has been the origin of a number of terms to designate the disease. Wunderlich used multiple *lymphadenoma* without leukemia. Blioth gave it the name *malignant lymphoma*. Sternberg introduced the term *lymphogranuloma*. There have been other terms and other combinations. Although the name Hodgkin's disease is far from ideal, perhaps it will serve as well as any term until the true nature of the syndrome has been established.

Hodgkin's disease is characterized by progressive enlargement of the lymph nodes, fever, which is more pronounced in the terminal stages, moderate anemia, and often a fatal outcome. It affects those of all walks of life, of any age and of either sex. It is more frequently observed, however, in young males. It is not inherited, and there is no evidence of direct contagion. Its frequent occurrence in the cervical nodes suggests an oropharyngeal portal of entry. The specific etiologic agent is unknown.

Pathologically, the early enlargement of the nodes is characterized by lymphoid hyperplasia. This is so extensive that the normal appearance of the node is soon lost. It is sometimes difficult to differentiate these nodes microscopically from chronic septic nodes. Later the Dorothy Reed cells become evident and many eosinophile leukocytes. At this time the microscopic appearance is characteristic with the added fibrosis and complete disorganization of the normal lymphoid structure. During the early stages the nodes are discrete, freely movable, and of a homogeneous grayish appearance when sectioned. They have a peculiar elastic consistency on palpation. When exposed for biopsy the appearance of a group is characteristic. This stage may persist for a long time. Later progressive scarring ensues and the nodes fibrose and may fuse. Lymphoid cells invade the capsules and further dissemination may occur. During this invasive stage any tissue of the body, even bone and the central nervous system, may be secondarily invaded. This termination presents the characteristics of malignancy. It has been so recognized in fact. Ewing has designated it *Hodgkin's sarcoma*. The entire pathologic picture is perhaps best rationalized when considered as an infectious granuloma with subsequent malignant change.

Symptoms—Clinically the onset is in

sidious. The patient may notice some malaise. However the discovery of the disease is in finding the enlarged painless nodes. These are usually originally observed in the neck and on one side. The progressive enlargement is ordinarily slow. Gradually other groups of nodes enlarge and then nodes in other regions. Fulminating forms are described. The characteristic cervical axillary and inguinal nodes are easily palpable. The x-ray readily demonstrates the enlarged mediastinal nodes. The spleen enlarges and is palpable at the costal margin in about half of the late cases. The duration may be a matter of months. The usual course is from two to four years. It may persist in sclerosing forms for many years. The termination is characterized by widespread invasion of the entire body.

The fever is of the Pel-Ebstein type. There is marked lassitude and weakness. The basal metabolism may be elevated in progressive cases. Pruritus is commonly encountered even early in the disease. In patients with unexplained weakness and fever Hodgkin's disease should be considered. Pigmentation may appear and cutaneous granulomas. Hemorrhage is rare. Terminally emaciation and weakness reach an extreme degree.

According to Wiseman three types of blood pictures are encountered. In about half the patients there is found leukopenia, lymphopenia, eosinophilia of from 8 to 10 per cent and monocytosis. The anemia is of the hemoglobin type. The erythrocytes are decreased and the color index is lowered. The platelets are increased. In another 40 per cent the findings are similar save that eosinophilia is lacking. In 5 per cent there is neutrophilic polymorphonuclear leukocytosis the count ranging from 10,000 to 40,000. There is a relative decrease in the lymphocytes, monocytes and eosinophils. About 5 per cent of the pictures are mixtures of these.

Treatment.—Treatment by medication has little effect. Iron and arsenic have been tried. Early excision followed by intensive radiotherapy has been practiced. Since lymphoid tissue is so susceptible to radium and x-ray therapy this form of management is the most common. Even these results are unsatisfactory.

LYMPHOSARCOMA

Lymphosarcoma is a malignant tumor originating within the lymph nodes. It may arise in other lymphoid tissues for example in the tonsil. Its existence as a clinical entity has been questioned. This applies particularly to the generalized form *lymphosarcomatosis* described by Kundrat in 1893. Others regard the localized form as a primary sarcoma. It presents certain resemblances to Hodgkin's disease. There is evidence of blood stream metastasis. In certain cases the tumor cells have been found in the blood stream. This variation has been termed *leucosarcoma*.

Lymphosarcoma of the localized form presents a varying microscopic picture, depending on the type of cell of which the tumor is composed. Three varieties are recognized: (1) The lymphoblastoma type is composed of large round cells, the lymphoblasts; (2) the lymphocytoma is formed by small round cells; and (3) the third form originates from the reticular cells and is designated a reticular cell sarcoma. These three forms are not distinguishable clinically.

The disease is more common in males. It occurs at all ages but usually during middle life. Local infiltration occurs early and is the common finding. Later fever may occur. During the early stages it is difficult to differentiate it from Hodgkin's disease or forms of leukemia. The mediastinal cases are recognized by means of the x-ray. The disease is uniformly fatal and the course usually shorter than that of Hodgkin's disease.

Treatment.—Treatment is by excision of the localized forms with subsequent intensive radiation. X-ray treatment may be of benefit. All treatment is unsatisfactory and cures are unknown.

LYMPHATIC LEUKEMIA

Lymphatic leukemia is a blood disease characterized by progressive enlargement of the lymph nodes and a great increase in the number of circulating lymphocytes. There is usually a moderate anemia. In the *leukemic form* the total leukocyte count is not characteristic although there is lymphocytosis. Other lymphoid tissues are involved.

The lymph nodes are greatly enlarged. They may adhere to one another but do not fuse. They do not adhere to the skin or ulcerate. The involvement is general and usually occurs throughout the body. Biopsy reveals soft discrete nodes. When sectioned these are moist, grayish and of homogeneous consistency. Microscopically the reticular framework is packed with lymphocytes. These vary in size in different nodes. It is thought that nodes containing a preponderance of large lymphocytes occur in the more acute conditions.

Two types are recognized. An acute form occurs in children and may prove fulminant and rapidly fatal. The lymph nodes rapidly enlarge. They are soft and do not fuse. Subcutaneous and submucous hemorrhages appear. Fever occurs and anemia is marked. The chronic form occurs in older persons. It is intermittent and may continue for years. Anemia is noted and also weakness. The enlarged lymph nodes and the blood picture are characteristic.

Treatment—Treatment of the acute form is unsatisfactory. Medication is of no avail. Radiotherapy of the chronic forms is at best palliative.

ENDOTHELIOMA

Endothelioma develops as a primary tumor originating in the endothelial lining of the lymph sinuses within the lymph nodes. It is rarely encountered. It has been confused with secondary carcinoma of the node. It may become generalized. It is not diagnosed clinically and as a rule is only recognized during the study of microscopic sections of the nodes. In the neck it becomes extensive and metastases occur. Endotheliomas are particularly susceptible to radiotherapy. They have been discussed under lymphatics.

Chloroma is characterized by the occur-

rence of greenish tumors of the skull vertebrae, ribs and other organs accompanied by a leukemic blood picture. It appears to be a systemic disease of the lymphatic system. The tumors are of mesenchymal origin. It occurs chiefly in young males, runs a rapid course and terminates fatally. The lymph nodes and spleen are enlarged. Invasion and secondary deposits occur. The color of the tumors is characteristic. It has been regarded as due to transformed blood pigment or to fatty products of cell metabolism. Greenish refractive lipid granules are found in the tumor cells. Chloroma presents a leukemic process with a definite neoplastic trend. It belongs with the sarcomas of the blood-forming organs. The etiology is unknown.

THE DIFFERENTIAL DIAGNOSIS OF LYMPHADENOPATHY

A number of significant features should be considered in making a differential diagnosis of a given lymphadenopathy. These have been recently summarized by Wiseman, an abridged account of whose work is here presented. Knowledge of the tributary lymphatics is indispensable as it aids in determining the portal of entry for malignant cells or for infection. Five differentiating criteria are then important: fever, characteristics of the nodes, splenomegaly, the blood picture and the biopsy findings.

Fever indicates an infectious lymphadenopathy. It is however present in acute leukemia, serum sickness and in the terminal stages of any lymphadenopathy. The septic type indicates suppurative lymphadenitis. The Pel-Ebstein type suggests Hodgkin disease. On the other hand, absence of fever does not rule out infection.

Significant characteristics of the nodes include tenderness, distribution and consistency to palpation. Tender nodes indicate infection and resultant inflammation. Distribution may be general or local. Local enlargement without fever or tenderness suggests lymphosarcoma, metastatic malignant growth, benign hypertrophy, tertiary syphilis or Hodgkin's disease. Local swelling with fever and tenderness indicates tuberculosis or pyogenic lymphadenitis but never Hodgkin's disease. Generalized lymphadenopathy

without fever occurs in the chronic leukemia the afebrile phases of Hodgkin's disease and the benign hypertrophies. Generalized enlargement with fever may mean syphilis. Hodgkin's disease, infectious mononucleosis, generalized lymphatic tuberculosis (which is rare), serum sickness or an acute phase of leukemia.

Fluctuant nodes may be tuberculous or pyogenic. In leukemia the nodes are always discrete and elastic. Some forms of metastatic carcinoma result in hard unyielding glands as do sclerosing types of Hodgkin's disease but many do not.

Splenomegaly is a clinical aid. A large firm spleen accompanied by generalized enlargement of the nodes nearly always signifies leukemia. In Hodgkin's disease the spleen is palpable in about half the cases. In infectious mononucleosis the spleen may be somewhat enlarged. Occasionally lymphosarcoma presents a palpable spleen. Chronic cervical enlargement with a palpable spleen strongly suggests leukemia or Hodgkin's disease.

The *blood picture* is one of the most important criteria but it must be carefully studied. It is normal in the malignant enlargements save in the advanced stages or when accompanied by leukemia. In leukemia it is diagnostic. A neutrophilic leukocytosis is evidence that the lymphadenopathy

is infectious. Lymphatic tuberculosis presents lymphocytosis, monocytosis and mild anemia of the hemoglobin type. Hodgkin's disease reflects lymphopenia, eosinophilia and monocytosis with usually leukopenia and marked anemia. Eosinophilia and lymphocytosis with normal red and white cells suggest syphilis. Marked lymphocytosis, Reid nuclei and normal red cells suggest infectious mononucleosis. Pyogenic lymphadenitis presents principally a neutrophilia. The non-infectious non-malignant lymphadenopathies are characterized by normal total counts but a relative lymphocytosis. Aleukemic lymphatic leukemia may be eliminated by demonstrating the concurrent disease responsible for the lymphatic reaction.

Biopsy may be necessary. The largest node should be completely removed. It is well to remember that the cervical nodes lie deeper than the superficial fascia and among important structures. Careful study of biopsy material coupled with painstaking clinical investigation will doubtless lead to more light in an admittedly uncertain field. There too lies a way to clinical progress.

XII. THE ENDOCRINE SYSTEM

DISEASES OF THE THYROID GLAND AND THEIR MANAGEMENT

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

Embryology—The thyroid gland* is a derivative of three primordial structures one median and two lateral. The median thyroid component which contributes the most important part of the thyroid gland first appears as a well-defined lobe or evagination in the ventral wall of the primitive pharynx at the point at which the *tuberculum impar* and the two lateral anlagen of the tongue join between the first and second pharyngeal pouches. This occurs in the embryo of 3 to 5 mm., or before the second pair of somites has been definitely separated off and according to Weller consists in a proliferation rather than in a primary differentiation of pharyngeal cells (entoderm) (Fig 105). As growth takes place the fold becomes a spherical body which in turn soon becomes lobed and for a time is continuous with the pharynx by a narrow pedicle. The point in the pharynx to which the pedicle is attached is later indicated by the depression in the tongue the *foramen caecum* behind the apex of the V row of the circumvallate papillae. This pedicle normally disappears as the median thyroid epithelium sheet like in form descends in the neck finally to occupy a position astride the upper portion of the trachea. Occasionally however the pedicle persists in part or in whole to form the *thyroglossal duct* a narrow tube extending through the center of the tongue for a variable distance toward the thyroid gland.

The lateral thyroid components arise as evaginations from the fourth entodermal pouch and cannot be identified until the embryo contains more than twenty somites. These situated laterally and inferiorly with regard to the median body move forward and upward to meet the posterior surface of the latter. According to Weller, the three primordial structures fuse in the

13 mm embryo into a morphologically single structure which however histologically is composed of two distinct types of tissue. The median thyroid component consisting at this stage of the more differentiated tissue, undergoes little change but that of growth until the lateral thyroid bodies in their entirety, are similar in appearance. Then begins differentiation of the sheets of epithelium into follicles throughout the entire gland.

Anatomy—The thyroid gland which is red-fleshed in appearance and is the largest of the ductless glands is normally concealed by the overlying infrahyoid and sternocleidomastoid muscles and lies in the lower third of the neck partially encircling the upper portion of the trachea and the lower portion of the larynx. Its configuration is roughly that of a butterfly consisting of two lateral lobes connected in front of the trachea by a narrow strip the *isthmus*. Although the organ is symmetrical in plan not infrequently one lobe usually the right is appreciably larger than its fellow. The size and weight of the gland vary greatly depending on the age sex physiologic status and place of residence of the person. The average size may be roughly stated as follows: vertical diameter 3 to 6 cm. anteroposterior diameter 2 to 3 cm. transverse diameter (whole organ), 6 to 7 cm. Normally its weight ranges from 20 to 60 gm., averaging about 40 gm. The lateral lobes one on either side of the trachea are irregularly pyramidal or conical in form presenting three surfaces: a convex anterolateral a grooved posterior and a concave internal. The upper extremity of the lobe narrows to an apex the *superior pole*. The lower extremity which is thick and rounded is referred to as the *inferior pole*.

The isthmus commonly about 2 cm in breadth and 0.5 cm in thickness covers usually the second and third tracheal rings and joins each lateral lobe at the junction of its middle and lower thirds. This likewise varies considerably in size shape and situation and occasionally is absent.

In at least 50 per cent of cases there is present an upward prolongation of thyroid tissue the *pyramidal process* which arises from the isthmus or the anteromedial border of either lobe and extends as a ribbon or cord like structure just lateral to the median lobe for a variable distance toward the hyoid bone. Occasionally it is free of any connection with the thyroid gland. The surgical importance of the pyramidal process lies in the fact that since its position is above the operative field usually exposed in an operation for goiter it may be readily overlooked during the resection. In that event almost invariably the process subsequently enlarges to produce a disfiguring deformity to annoy the patient and to plague the surgeon.

The thyroid gland is completely encased in a laxal sheath derived from the middle layer of deep cervical fascia and commonly referred to as the *surgical capsule* in distinction to differentiate it from the *true capsule*. The latter is a very thin transparent covering

* There has existed among embryologists a sharp division of opinion with regard to the mode of development of the thyroid gland in man. The controversy has centered about the question as to whether the thyroid gland is derived solely from a single median primordial structure or whether its derivation includes three two lateral and one median. The earlier investigators Born (1883) His (1883) and others concluded that the thyroid gland arose from three primordial structures. Further researches in comparative embryology led others to deny that the lateral post-branchial bodies played any part in the development of the thyroid gland. More recently, however the view has prevailed that although the lateral bodies do not function in the lower vertebrates in man they fuse with the median body and form an integral part of the definitive thyroid gland.

inseparably attached to the parenchyma of the gland. The surgical capsule is attached to the true capsule by loose areolar tissue which offers but little resistance to its separation during the course of an operation. For the most part, this fascial sheath is thin in places imperfectly formed it readily yields to enormous enlargements of the gland and at times permits the escape of adenomatous projections beyond its confines. Contained within this fascial compartment are the thyroid gland the upper extremity of the trachea the cricoid and thyroid cartilages and commonly all four parathyroid glands. The inferior laryngeal nerve is generally considered to run within the compartment, but according to Pool and Falk it actually lies outside, between two layers of fascia split off posteriorly from the surgical capsule. To the trachea and cricoid and thyroid cartilage the thyroid gland is so firmly attached by means

of *road arteries* and occupies a position for the most part medial to the gland. Usually the nerve is posterior to the gland only in relation to the inferior pole. The medial position of the nerve becomes more pronounced in gouty glands.

Structure.—The *fibroelastic capsule*, which envelops the gland completely, gives off numerous septums which together with blood vessels, lymphatic structures and nerves ramify through the substance of the gland to subdivide it into compartments of irregular size and shape. The earlier belief based on microscopic study of the occasional section held that these septums subdivided the parenchyma into isolated portions completely surrounded by connective tissue but the recent investigations of Reinhardt based on study of wax models of the gland reconstructed from serial sections indicate that there are no distinct lobules but

Fig. 105.—A Lateral aspect of the pharyngeal and primordial epithelium of the 4 mm embryo. The median and lateral thyroid components are situated much farther ventrally than the other primordia. B ventral aspect. The primordium of the median thyroid is situated just anterior to and midway between, the primordia of the tonsils. The primordia of the lateral thyroids extend laterally beyond those of the thymus components but are not in contact with ectoderm as are the latter (Waller).

of the fascial sheath and bands that it follows their movements as during the act of swallowing. Knowledge of this feature is of great importance in distinguishing clinically tumors of the thyroid gland from those arising from other adjacent structures. Two well-defined bands of considerable constriction are the paired suspensory ligaments. These arise from the anterior surface of the lateral lobe near its junction with the superior border of the isthmus and pass upward to be attached to the anterior surface of the cricoid and thyroid cartilages. The anatomical relationship between the thyroid gland the carotid sheath the inferior (recurrent) laryngeal nerve and the parathyroid glands is of prime importance to the surgeon. The carotid sheath is commonly lateral to the normal gland and posterior or posterolateral to the enlarged gouty gland. The nerve which normally runs in the tracheocephalic groove may lie anterior or posterior to the inferior thy-

roid gland instead the parenchyma is subdivided into large portions that have the shape of lamellar plates stalks and limbs joined by connecting bars or strips of thyroid tissue.

The structural unit of the gland is the follicle or vesicle a closed sac of varying size and shape. The follicle is lined by a single layer of epithelium normally cuboidal or low columnar which rests directly on the surrounding connective tissue without interposition of a basement membrane. Within the cell in addition to the nucleus and nucleolus are protoplasmic filaments the mitochondria, visible only by means of special staining. It has been claimed that these become more conspicuous in the active phase of the cells than in the resting phase and accordingly the activity of the gland may be judged by the conspicuousness of these filaments. Usually found filling the follicle is a viscid homogeneous acid staining substance called the phys-

ical properties of which vary according to the activity of the gland. In the very active gland the follicles are relatively small with high columnar epithelium and only partially filled with a thin poorly staining colloid whereas in the resting or sluggish gland the follicles lined with flattened cells are distended by the accumulation of a more viscous and deeply staining colloid.

Fig. 106.—Section of a normal thyroid

loid (Fig. 106). The presence of rests of fetal cells situated between normal adult follicles as first described by Wölfler and subsequently often included in descriptions of the histology of the gland is denied by Rienhoff. The latter observer has explained that a tangential section through the dome of an underlying follicle may give the appearance of an isolated group of epithelial cells.

Blood Supply.—The thyroid gland has an exceedingly generous blood supply (Fig. 107) derived principally from the superior and inferior thyroid arteries on each side and augmented constantly by collateral vessels from the trachea and esophagus and occasionally by the thyroid ima, a vessel springing directly from the arch of the aorta. The superior thyroid artery, the first branch of the external carotid, joins the gland at the superior pole or medial to it and ramifies over the anterior and external surfaces sending branches into the interior. The inferior thyroid artery arises from the subclavian by way of the thyroid axis ascending in the neck to the level of the sixth cervical vertebra and passes medially behind the carotid sheath in front of or behind the recurrent laryngeal nerve to enter the thyroid gland near the posteromedial border usually at the level of the junction of the middle and lower thirds. As the artery enters the gland it divides into medial and lateral branches which anastomose freely with branches from the superior thyroid artery and with vessels from the trachea and esophagus. Commonly there is also free communication between the circulation of each lobe by way of branches across the isthmus. Surgically the collateral circulation is of great importance. In the operation of subtotal thyroidectomy, all four of the principal arteries to the gland can be safely ligated with little or no risk that the circulation to the remnant of the gland will be seriously impaired provided the remnant of the gland is not detached from the side of the trachea thereby

destroying its collateral circulation. The veins emerge from the interior of the gland to form a plexus of dilated vessels beneath the true capsule. From here there are three main channels of escape into the systemic circulation: the superior, the middle and the inferior thyroid veins. The superior veins usually two in number run along the course of the superior artery and drain into the internal jugular vein. The middle vein which is not always constant emerges as a single vein or a plexus of veins from the capsule on the lateral surface of the gland and passes backward and laterally to enter the internal jugular vein. The inferior veins usually two in number pass downward in front of or on the side of the trachea to drain into the innominate vein. Not infrequently there is an additional vein which emerges from the pyramidal lobe of the isthmus and empties into one of the anterior jugular veins.

Since the veins drain directly into the large venous trunks in the root of the neck or in the upper mediastinum a vein insecurely ligated in the course of an operation for goiter may result in aspiration into the vein of a large quantity of air, with alarming symp-

Fig. 107.—Anterior view of the thyroid gland showing the arrangement of the principal blood vessels. AV, Accessory thyroid vein; SV, superior thyroid vein; MV, middle thyroid vein; LV, inferior thyroid vein; LA, superior thyroid artery; PL, pyramidal lobe.

tons. Guthrie has reported seventeen instances of air embolism occurring on the services of twelve surgeons during the course of an operation for goiter; in six cases the outcome was fatal.

Lymphatic Structures.—The thyroid gland possesses a rich lymphatic circulation. From lymph spaces surrounding the follicles, intercommunicating channels run

with the interlobular septums to the periphery where they unite to form under the capsule an intricate plexus of vessels completely surrounding the gland. The vessels leave the gland peripherally from three portions—the superior pole, the inferior pole and the lateral aspect of the lobe and drain into nodes in the deep cervical region and into those in front of and lateral to the trachea. Occasionally lymphatic vessels empty directly into the subclavian vein without interposition of lymph nodes.

Nerve Supply.—The gland is innervated by fibers derived for the most part from the sympathetic system. According to Joll they leave the spinal cord with the first two thoracic roots and pass to the inferior middle and superior cervical ganglia. Non-medullated fibers from all three ganglia enter the gland as plexuses of fine fibers in intimate association with the inferior and superior thyroid arteries. It is probable that fibers from both superior and inferior laryngeal nerves also contribute partly to the nerve supply of the thyroid gland.

Physiology.—The function of the thyroid gland is so far as is known to elaborate thyroxine and to deliver it or a substance containing it to the blood stream. Thyroxine the active principle of the thyroid gland was isolated by Kendall in 1914 and was synthesized by Harrington in 1927. The formula assigned to it by Harrington is as follows:

H. S. Plummer in 1917 stated the following hypothesis: 1. Thyroxine is active in nearly all or all of the cells of the body. 2. Thyroxine is a catalytic agent hastening the rate of formation of a quantum of potential energy available for transformation on excitation of the cells.

The administration of thyroxine or of the thyroid gland substance results in increase in the basal metabolic rate and in the physiologic phenomena that would be expected to result from this increase in the rate of transformation of energy. The pulse rate and pulse pressure are increased. The minute volume output of the heart is increased. The surface temperature of the body is increased and perspiration is increased. There is loss of body weight unless the intake of food is increased sufficiently to counterbalance the effect of the increased metabolism. There is tremor. The cholesterol in the blood

decreases in amount. If the administration of a preparation of thyroid is persisted in sufficiently long and if it is given in sufficient quantity, auricular fibrillation may develop.

Thyroxine has an effect on the myocardium that is not attributable to any effect produced through the nervous system. Priestley Markowitz and Mann found that the heart of a pup anastomosed to the vessels in the neck of a dog beat at an increased rate when the dog was given thyroxine. Markowitz and later then studied tissue cultures of pulsating fragments of heart muscle removed from chick embryos before the appearance of nerve elements in the heart. They found that thyroxine produced in these fragments a progressively greater increase in the rate of pulsation ending in some cases in fibrillation and paralysis.

Boothby has shown that following a single injection of a large amount of thyroxine the basal metabolic rate rises for about ten days after which it falls rapidly for a time then gradually until it reaches the preinjection level approximately from eight to ten weeks after the injection.

Thyrotropic Hormone.—There has been isolated from the anterior lobe of the pituitary gland a substance which when injected parenterally into animals causes hypertrophy and hyperplasia of the thyroid gland (Loeb and Bassett and Aron). In man this substance causes an increase in the basal metabolic rate which however is not maintained for longer than a few weeks (Thompson). The same substance administered to some animals causes exophthalmos, the degree of protrusion of the eyes being greater if the thyroid gland is removed before the injection (Marine and Rosen and Friedgood). Paulson has shown that this protrusion is due in part at least to an increase in intraorbital fluid. Recently Rundle and Pochin have found an increase in fat in the extraocular muscles and the orbital fibrofatty tissue of patients with exophthalmic goiter. Dobyns has found an increase in fat in the extraocular and other skeletal muscles of animals following production of exophthalmos by thyrotropic hormone. Rawson has found that the thyroid stimulating hormone of the pituitary body is inactivated by thyroid tissue and also by lymphoid tissue.

The inactivated hormone may be reactivated by heat.

Two series of goitrogenic substances have been found to cause hypertrophy of the thyroid parenchyma and to cause diminution of function. The action of one series which includes cabbage (Chesney, Clawson and Webster), evanates (Marine) and potassium sulfocyanate (Rawson) is prevented by iodine. The action of the other series which includes sulfonamides and related drugs and thiouracil, thiouracil and related drugs (MacKenzie and MacKenzie Astwood) in causing hypertrophy of the thyroid parenchyma is not prevented by iodine but is prevented by the administration of desiccated thyroid or thyroxin. The thiouracil group interferes greatly with the entrance of iodine into the thyroid gland. The hypertrophy of the thyroid parenchyma is mediated through the anterior lobe of the pituitary body.

Other physiologic considerations will be taken up under the various diseases of the thyroid gland.

Classification of Diseases of the Thyroid Gland—The term goiter or struma is loosely employed to embrace any abnormal enlargements of the thyroid gland. Many classifications of goiter have been advocated based on etiological, functional, structural or clinical features, or on a combination of two or more of these. Since most of the groupings have proved unsatisfactory in clinical practice they will not be submitted here, lest the multiplicity of terms provoke unnecessary confusion. The following clinicopathologic classification founded on Plummer's conception of the diseases of the thyroid gland has proved eminently satisfactory for the grouping of the many thousands of cases seen in the Mayo Clinic.

- 1 Diffuse colloid goiter
- 2 Adenomatous goiter without hyperthyroidism
- 3 Adenomatous goiter with hyperthyroidism
- 4 Exophthalmic goiter
- 5 Thyroiditis
 - Acute
 - Chronic
 - Non specific
 - Tuberculosis
 - Syphilis
 - Actinomycosis

- 6 Myxedema
- 7 Cretinism
- 8 Malignant diseases
- 9 Congenital abnormalities

DIFFUSE COLLOID GOITER (ADENOMATOUS GOITER, ENDEMIC GOITER)

Diffuse colloid goiter is characterized grossly by a diffuse symmetrical enlargement of the thyroid gland and pathologically by distention of the follicles with increased amounts of colloid and flattening of the follicular epithelium.

Etiology—Various theories have been proposed as to the cause of diffuse colloid goiter. Marine's work in prevention of sim-

Fig. 108—A patient with a colloid goiter.

ple goiter by the administration of iodine and the work of many others along similar lines indicate that deficiency of iodine plays an important etiologic role. McCarrison's studies in India indicate a bacterial factor in the etiology of endemic goiter, and Marine and Lenhart found a similar factor in the colloid goiters of fish.

Pathology—The thyroid is symmetrically and smoothly enlarged. The cut surface glistens from the increased amount of colloid and distended follicles are occasionally large enough to be identified with the naked eye. Microscopic sections disclose distention of the follicles with colloid that stains homogeneously. The alveolar epithelium is flattened.

Clinical Considerations.—Diffuse colloid goiter occurs most frequently at, or soon after, the age of puberty (Fig. 108). It is more common among females than among males. The thyroid gland is symmetrically enlarged. It is somewhat softer than the normal gland. In some instances vascularity of the gland is so greatly increased that arterial bruits may be heard over the gland. In these cases the gland is usually extremely soft. Enlargements sufficient to cause respiratory disturbances from pressure are extremely rare. The gland may enlarge from time to time, particularly during the menstrual period or during pregnancy. Colloid goiters large enough to necessitate treatment are becoming rare in this country.

There are no constitutional symptoms associated with colloid goiter. The basal metabolic rate is usually near the lower level of normal limits. It may be somewhat below normal.

The differential diagnosis offers no difficulty except when colloid goiter is associated with neurasthenia or neuroses of the types that suggest, from their symptoms, mild degrees of hyperthyroidism. The differential diagnosis in such cases will be discussed under the hyperthyroid states.

Treatment.—Marine has shown that colloid goiter can be largely prevented by the administration of small amounts of iodine over long periods. He has advised the use of small doses of iodine in childhood as a prophylactic against colloid goiter.

When colloid goiter has become established, iodine does not usually cause much diminution in the size of the enlarged gland. Ordinarily, however, the enlargement and bruit will subside rapidly if desiccated thyroid is given orally or if thyroxin is given intravenously. It is important to regulate the dosage of desiccated thyroid by means of repeatedly estimated basal metabolic rates. Occasionally, when the colloid goiter has been reduced, adenomas which could not be felt previously will become apparent. These ordinarily will not diminish appreciably in size with continuance of treatment. Surgical resection of the gland is seldom indicated, except in those cases in which marked obstructive dyspnea is present or in those cases in which the process is associated with adenoma.

ADENOMATOUS GOITER WITHOUT HYPERTHYROIDISM (NON-TOXIC NODULAR GOITER)

Under the term adenomatous goiter are included the discrete, encapsulated, or partially encapsulated, adenomas of the thyroid gland, and in addition nodular enlargements of the thyroid gland occasionally are referred to as "adenomatosis." Adenomas may be single or multiple.

Etiology.—Adenomatous goiter occurs with greatest frequency in those geographical districts where colloid goiter is endemic. Adenomas often appear in association with or as sequelae of, colloid goiter. It is prob-

Fig. 109—Karyogram of an intrathoracic goiter occupying a position behind the trachea.

able therefore that deficiency of iodine is one factor in the causation of adenomatous goiter. Among the views regarding pathogenesis may be mentioned the following: Adenomas may arise (1) from fetal epithelium (Wolfer), (2) as "involutional bodies" (Rienhoff), (3) from maldeveloped tissue rudiments (Kloepfel) and (4) as circumscribed regenerative and compensatory new formations (Wegelin).

Pathology.—Adenomatous masses in the thyroid gland may be true tumors, completely or partially encapsulated, or they may occasionally be nodular masses without capsules. The tissue in adenomas may be of

the fetal type of thyroid tissue or it may be identical with the adult type of thyroid. Regions of degeneration with deposition of cholesterol crystals formation of cysts

Fig 110—Diagram of a substernal goiter showing the tracheal displacement

hemorrhage deposits of calcium salts and occasionally regions of thyroiditis are found frequently in adenomas. Regions of hypertrophy of the follicular cells frequently are

appear most commonly in the first half of adult life. The gland presents a nodular enlargement usually asymmetrical which may in some instances reach a huge size. Substernal projections of the goiter should be suspected and looked for in roentgenograms of the chest whenever the lower poles of the thyroid are not easily palpable (Fig 109). In rare instances the entire goiter may be in the substernal position. Tracheal pressure and displacement are frequently seen especially when the nodular enlargement is wedged into the superior thoracic strait (Fig 110). When pressure is sufficiently great a respiratory stridor easily can be heard during forced breathing through the open mouth. Dilatation of the superficial veins of the anterior thoracic wall may occur as a result of pressure on the great veins in the neck (Fig 111).

Even small adenomas may be so situated that they cause pressure on the recurrent laryngeal nerve with resultant paralysis of the corresponding vocal cord. This may produce no symptoms and is detected only on laryngeal examination. Hypertrophy and carcinoma of the thyroid occurring in pa-

Fig 111—Photograph taken with an infra red plate showing the veins of the chest dilated as a result of venous obstruct from a substernal goiter

found in the tissue immediately surrounding the adenoma or in the adenoma itself.

Clinical Considerations—Adenomatous goiters may be present at birth or may become apparent at any time in life. They

patients with adenomatous goiters will be considered later.

Treatment—Prophylactic treatment with iodine directed against colloid goiter may reduce the incidence of adenomatous goiter.

Administration of iodine or preparations of thyroid sometimes will reduce the size of adenomatous goiters, but there seems to be no advantage in this procedure and it seems probable that the prolonged administration of iodine to patients who have adenomas of the thyroid sometimes will predispose to hyperfunction of the adenoma. Surgical removal of the adenoma is the treatment of choice.

When the adenoma is causing respiratory obstruction because of tracheal pressure it is imperative that they be removed. It is desirable to remove adenomas 1 inch (2.5 cm.) or more in diameter whether they are producing symptoms or not, as the risk of removal from otherwise healthy persons is negligible and the possibility of subsequent trouble from hyperthyroidism, tracheal pressure or the development of carcinoma in the adenoma is sufficiently great to make presence of the adenoma undesirable. Recurrence of adenomatous goiters occurs more frequently in those cases in which the patient is operated on before the age of twenty-five years than in those in which the operation is performed at a later period of life. Because of this fact when children and young adults have nodular goiter, surgeons commonly advise that operation for the removal of the nodules be postponed until the patient is twenty-five or thirty years of age. However, Kennedy found that in twelve of sixty-two patients who were fifteen years old or younger from whom nodular enlargements of the thyroid gland were removed, carcinoma was present. Such a high incidence of carcinoma of the thyroid in young persons makes necessary a careful consideration of thyroid enlargements in all cases, regardless of age. The operative procedure indicated is removal of all the nodules contained in the gland. For a single adenoma, unilateral resection will suffice, but in the majority of cases both lobes are involved by nodular formation and bilateral resection should be performed. A nodule in the lobe which appears clinically to be the smaller may be readily overlooked if at operation the lobe is not thoroughly exposed. In that event subsequent growth of the nodule is likely to occur, resulting in so-called recurrence of the adenomatous goiter.

THE HYPERTHYROID STATES

H. S. Plummer classifies the hyperthyroid states as (1) hyperfunctioning adenomatous goiter and (2) exophthalmic goiter and recognizes these as two separate clinical entities. In hyperfunctioning adenomatous goiter the physiologic status is identical with that produced by feeding excessive quantities of desiccated thyroid.* Exophthalmic goiter on the other hand is characterized by certain additional phenomena which cannot be reproduced by the administration of thyroid. These phenomena are (1) the ocular phenomena (exophthalmos, stare, edema of the eyelids and so forth), (2) the characteristic psychic status, (3) frequent useless purposeful movements, (4) a tendency to the development of gastrointestinal crisis, and (5) the presence in nearly all cases of diffuse hypertrophy of the thyroid.

Puppel and Curtis, studying the iodine balance in toxic nodular goiter among patients maintained on a low iodine intake, found a great increase above normal in the excretion of iodine, particularly through the urine. The total excretion of iodine was greater than in cases of exophthalmic goiter in the latter condition the greatest increase in excretion was through the feces. The excretion of iodine from patients who had toxic nodular goiter simulated that of a hypothyroid patient after treatment with desiccated thyroid. Puppel, Klishon and Curtis also found a decrease in excretion of calcium in toxic nodular goiter when compared with that in exophthalmic goiter.

ADENOMATOUS GOITER WITH HYPERTHYROIDISM

(Toxic Adenoma, Hyperfunctioning Adenomatous Goiter)

Hyperthyroidism attributable probably to hyperfunction of adenomatous tissue is prone to develop in cases of adenomatous

* If one reasons by analogy to other ductless glands, function of adenomas of the thyroid seems reasonable. Some evidence that adenomas of the thyroid gland may overfunction are as follows: (1) In a patient who has the clinical syndrome of hyperfunctioning adenoma is goiter and a single adenoma of the thyroid is resected, the adenoma will cure the hyperthyroidism. (2) In a case of mixed case with adenoma of the thyroid hyperthyroidism occurred. At operation the thyroid was markedly atrophic but retained a few adenomas.

goiter Plummer has pointed out in this condition the absence of the phenomena noted in the foregoing as characteristic of exophthalmic goiter He stated The primary clinical manifestations of the hyperthyroid state associated with adenomatous goiter are or are due to the reactions that must accompany elevation of the rate of energy transformation in the body (1) cardiovascular reactions that are indicative of an increased minute-volume flow of blood from the heart, (2) increased perspiration and surface temperature indicative of an elevation of heat elimination (3) increased food consumption in most instances insuffi-

Fig. 112.—A patient who has a adenomatous goiter with hyperthyroidism

cient to maintain the body weight (4) a group of findings attributable to stimulation irritability and fatigue of the nervous system The physiologic status of the patient with hyperfunctioning adenomatous goiter can be reproduced by the administration of excessive quantities of thyroid or thyroxin

Pathology.—In general the pathologic findings are similar to those in cases of adenomatous goiter without hyperthyroidism Regions of hypertrophy in adenomatous tissue or in the tissue outside the adenomas are somewhat more frequent in hyperfunctioning adenomatous goiter than if hyperthyroidism is not present but intra-adenomatous hypertrophy is found with such

great frequency in glands from patients with no evidence of hyperthyroidism that it can not be considered characteristic When extra-adenomatous hypertrophy is present it is found in localized regions and is not diffuse

Clinical Considerations.—The symptoms of hyperthyroidism associated with hyperfunctioning adenomatous goiter (Fig. 112) are those that would be expected to accompany an increase in the basal metabolic rate that is nervousness tremor increased sweating and sense of heat loss of weight and tachycardia In addition when the disease has existed for a long enough time auricular fibrillation is prone to occur If hyperthyroidism may be present for months before the patient is aware that an abnormal state exists and must frequently he consults a physician because of symptoms referable to the cardiac disturbances that accompany the condition Goiter usually has been present for years before symptoms appear the average duration being sixteen years The thyroid gland is enlarged asymmetrically and discrete adenomas are usually palpable Substernal extension of the goiter with tracheal displacement or compression occurs rather frequently The pulse and pulse pressure are increased and the circulation rate is increased Auricular fibrillation occurs in between a fourth and a half of the cases Cardiac decompensation occurs in many cases and may be due to the effect of hyperthyroidism on an already damaged heart or to long continued hyperthyroidism alone In the latter event cardiac decompensation probably occurs through the mechanism of auricular fibrillation or auricular flutter In some instances the cardiac features may so overshadow the clinical picture that the presence of hyperthyroidism may be overlooked and the condition mistaken for one of primary cardiac lesion The basal metabolic rate is usually moderately elevated above the patient's normal level The course of hyperfunctioning adenomatous goiter is usually slowly and steadily progressive If the condition is allowed to progress visceral degenerative changes usually appear If death supervenes it is usually dependent on such degenerative changes particularly of the heart and liver

Differential Diagnosis.—Hyperfunctioning adenomatous goiter is distinguished

from exophthalmic goiter by the absence of the characteristics of the latter disease when hyperthyroidism is present. In some mild cases there may be considerable difficulty in making a differential diagnosis. The presence of adenomas in the thyroid gland of a hyperthyroid patient does not suffice to make the diagnosis of hyperfunctioning adenomatous goiter for adenomas are present in the thyroids of from 20 to 30 per cent of the patients with exophthalmic goiter seen at the Mayo Clinic.

Many patients who have essential hypertension have increased surface temperature, nervousness, tachycardia and an increased basal metabolic rate. Frequently the basal metabolic rate will fall to a normal level if the patient is kept in bed constantly for a few days. Daily determinations of the metabolic rate are made. Under such circumstances the symptoms and signs suggesting hyperthyroidism usually also disappear.

The manifestations of many patients who have some form of neurosis, neurasthenia or comparable fatigue states simulate the manifestations of mild degrees of hyperthyroidism and the metabolic rate of these patients often is elevated. A most valuable procedure in such cases is the determination of a series of basal metabolic rates on consecutive days. Many neurotic patients after sufficient training in taking the test will exhibit a sharp drop in metabolic rate. Continuous elevation of the basal metabolic rate of a patient whose thyroid gland contains adenomas is best considered as evidence of hyperthyroidism.

Treatment—The treatment of a hyperfunctioning adenomatous goiter is partial thyroidectomy. The preoperative administration of iodine does not produce such striking improvement as it does in the patient with exophthalmic goiter but it seems beneficial in some cases. The treatment of complications will be considered under exophthalmic goiter.

The operative procedure indicated for this disease is similar in principle to that for adenoma without hyperthyroidism. However, if a patient has a bilateral enlargement with hyperthyroidism and is a poor surgical risk, either because of a severe degree of hyperthyroidism or because of the presence of degenerative processes, it is sometimes safer

to resect the goiter in two stages that is unilateral resection is followed after the lapse of two or three months by resection of the remaining lobe.

Prognosis—The prognosis in cases of hyperfunctioning adenomatous goiter is dependent on the amount of damage that has been sustained at the time the disease is brought under control. If there has been no permanent damage to the viscera, complete recovery follows removal of the adenomatous tissue and within two or three weeks after such a procedure the basal metabolic rate usually returns to normal. Even if a patient has a markedly decompensated heart during the course of hyperthyroidism, normal function of the circulatory system may be restored following relief of the hyperthyroidism. It is extremely rare for recurrences of hyperthyroidism from adenomatous goiter to occur after removal of all adenomatous tissue from patients who have hyperfunctioning adenomatous goiters.

Mortality—The mortality following thyroidectomy for adenomatous goiter with hyperthyroidism has been reported to be approximately 1 to 2 per cent. This mortality is dependent largely on complications of the disease.

EXOPHTHALMIC GOITER

(Graves' Disease, Basedow's Disease, Primary Hyperthyroidism)

Exophthalmic goiter is a constitutional disease probably caused by some unknown stimulus which acts on the thyroid gland, usually resulting in the production of excessive secretion of thyroxine and associated with certain characteristic phenomena which cannot be reproduced by the administration of thyroid or thyroxine but which may be the result of abnormal secretion from the thyroid gland. The phenomena resulting from the excessive secretion of thyroxine are as in cases of hyperfunctioning adenomatous goiter: the manifestations of increased metabolism or oxidative processes, that is, an increase in the circulatory rate, increased perspiration, intolerance to heat, increased appetite, loss of weight and weakness.

Characteristic Phenomena—In addition to the phenomena previously mentioned as occurring in adenomatous goiter with hyper-

thyroidism patients who have exophthalmic goiter usually present certain characteristic phenomena. Of these the most striking are the ocular disturbances. Exophthalmos is present in nearly half the cases. Retraction of the upper lids, contraction of the facial muscles around the eyes to produce a stare and edema of the lids are seen commonly in various combinations. Weakness of the ocular muscles occurs often, the commonest form being weakness of the elevators of the globe. Marked psychic instability with frequent emotional outbursts usually accompanies the severe untreated forms of the disease and useless purposeful movements are common. The most severe phase of the dis-

ease and the frequent presence of diffuse hyperplasia of these cells are resulting in papillary infoldings into the follicles. The follicular cells are columnar. The colloid is usually thin and stains poorly (Fig. 113 a). As a result of treatment with iodine the following histologic changes occur: (1) flattening of the epithelial cells, (2) increase in the amount and in the staining properties of the colloid, (3) apparent increase in the size of the follicles with diminution in number and size of the papillary infoldings and (4) decrease in vascularity and lymphocytic infiltration (Fig. 113 b). Lymphocytic infiltrations or accumulations of lymphocytes are frequently found throughout the gland.

Fig. 113.—a. Section of an exophthalmic goiter. The patient had taken no preparation of iodine. b. Exophthalmic goiter. The patient had taken crystals of iodine.

case is the gastrointestinal crisis which is characterized by vomiting and diarrhea, by intense restlessness and in the late stages by profuse sweating, a gray pallor falling blood pressure and jaundice. Death may occur although some patients recover from the crisis without significant treatment. Pneumonia frequently develops in the course of the crisis.

Pathology.—The thyroid gland is diffusely and symmetrically enlarged. It is firmer to palpation and more friable than the normal gland or colloid goiter. The vascular supply is greatly increased. The characteristic histologic change in exophthalmic goiter is the almost invariable presence of diffuse hypertrophy of the follicular cells

An encapsulated or partially encapsulated nodule or nodules (adenomas) with or without hypertrophy (intra-adenomatous) are found in a small percentage of thyroid glands in Graves disease. Their presence in the diffusely hypertrophic gland of Graves disease is coincidental and should not confuse the pathologist in distinguishing the histologic picture of exophthalmic goiter from that of adenomatous goiter with hyperthyroidism. The presence of *diffuse* extra-adenomatous hypertrophy throughout the entire gland in exophthalmic goiter and the absence of *diffuse* extra-adenomatous hypertrophy in adenomatous goiter with hyperthyroidism are the important distinguishing features.

Clinical Considerations—The diagnosis of exophthalmic goiter is dependent on recognition of the phenomena noted in the foregoing as being characteristic of the disease. Careful observation of the patient's behavior, motions and facial expression while the history is being taken frequently will give a clue to the diagnosis which might otherwise be missed. Exophthalmic goiter is of more frequent occurrence among females than males, the sex incidence varying in different clinics and in different years. The sex incidence, males to females, in the Mayo Clinic has varied from 1:4.69 to 1:1.53 during the past twenty years. Where is the disease most frequently afflicts patients who are between the ages of twenty and forty years, patients may be of any age. Of the historical evidence suggesting exophthalmic goiter, intolerance to heat, persisting and not recurring in flashes, loss of weight during a period when the intake of food is adequate and a fluctuating course with remissions and exacerbations and possibly crises are most important.

On physical examination the skin is found to be hyperemic and abnormally moist. The hands are usually warm. There is usually fine tremor of the extended fingers. The thyroid gland may or may not be considerably enlarged but is usually firm and easily palpable (Fig. 114), especially if palpation is carried out by the method long taught by Plummer. By this method the right lobe of the thyroid gland is felt by the examiner's left hand, the fingers are placed behind the sternomastoid muscle, the thumb in front and the thumb or fingers of the opposite hand are used to press the structures in the anterior part of the neck into the palpating fingers. The size, contour and consistency of the right lobe can be readily estimated by permitting the lobe to slip through the grasping fingers while the patient swallows. The opposite maneuver is used to examine the left lobe. Bruits over the superior thyroid vessels are often heard and thrills are occasionally felt in the same situations. Muscular weakness is usually a prominent feature in cases of moderate or more than moderate severity and may occasionally be marked in cases of mild degree. It can best be determined by having the patient step up on a high step. The fingernails occasion-

ally undergo a change which if present is nearly pathognomonic of exophthalmic goiter. The distal portion of the nail is separated irregularly from the underlying nail bed and there is a tendency for the nail to turn up at the end. When present this condition is usually bilaterally symmetrical.

Tachycardia is almost constantly present and the tachycardia of exophthalmic goiter is not usually slowed by pressure on the carotid sinus or by holding the breath after deep inspiration. The pulse pressure is considerably elevated, this being a very constant and important finding. The heart is frequently slightly enlarged and a bristly systolic murmur is often heard. The beat of the heart is forceful. Auricular fibrillation occurred in 22 per cent of cases of exoph-

Fig. 114.—Method of palpating the thyroid gland.

thalmic goiter in Wilkins and Boothby's series. It is transient in many cases but in others it may be permanent even after the disease has been controlled. Cardiac decompensation occurs more commonly in cases of independent heart disease but as Kepler and Barnes showed it may occur in cases of uncomplicated exophthalmic goiter. When it does so occur the mechanism by which decompensation occurs is usually auricular fibrillation or auricular flutter. Other cardiac irregularities are met occasionally in exophthalmic goiter.

The basal metabolic rate is elevated in the majority of cases; it is between +15 and +100 per cent or more.

Exophthalmos often is present, the total leukocyte count is normal. This finding is

not sufficiently constant or marked to be diagnostic

The concentration of blood cholesterol is lowered in cases of exophthalmic goiter. Perkin and Cattell expressed the opinion that the total concentration of iodine in the blood which usually is increased in hyperthyroidism is a better criterion in the differential diagnosis of thyrotoxicosis than the basal metabolic rate. Perkin and Lahey found that elevation of the concentration of iodine in the blood becomes less with increasing duration of the disease until after a year the concentration of iodine tends to be normal.

Recognition of Exophthalmic Goiter—Among recently graduated physicians the recognition of exophthalmic goiter is too frequently dependent on the classical signs and symptoms of the disease that is tremor, tachycardia, goiter and exophthalmos. Sometimes these are either absent or so slight that they are not noticed readily and the diagnosis of exophthalmic goiter is not even considered. Thus many patients who have mild exophthalmic goiter are suspected because of loss of weight, weakness and diarrhea, for example, of having carcinoma of the digestive tract and many are considered as primarily suffering from cardiac disease because of symptoms referable to the heart. Among the signs or symptoms that should lead to a suspicion of hyperthyroidism are unexplained loss of weight, especially suggestive if associated with a normal or excessive appetite, an increased pulse, pressure, weakness of the quadriceps muscles and intolerance to heat with increased sweating and a warm moist skin. The presence of auricular fibrillation always demands consideration of hyperthyroidism. Obviously, mild hyperthyroidism will be recognized only if the condition is kept in mind and its frequency is sufficiently great to justify bearing it constantly in mind.

Course of the Disease—If uncontrolled the course of exophthalmic goiter usually tends to be irregular waves of progression alternating with remissions which may be nearly or quite complete. Undoubtedly the disease would subside spontaneously in many instances if it were not interrupted by treatment. However, it is impossible to determine at any point in the disease what the

future course is to be. Occasionally mild exophthalmic goiter may exist for many years without causing intolerable disability. On the other hand in fulminating cases the patients may become extremely ill within a few weeks of the onset of the disease. Patients who have had the disease for years should be assumed to have degenerative visceral changes.

Differential Diagnosis—In general difficulties in diagnosis lie chiefly in the same groups of cases as were discussed under adenomatous goiter with hyperthyroidism and the problems often may be solved by the same means.

There is in addition one valuable diagnostic procedure which may be used in exophthalmic goiter. This is determination of the effect of iodine. Seven to ten days after beginning the oral administration of 10 minims of compound solution of iodine three times daily to a patient who has exophthalmic goiter there occurs a marked change in the patient's physiologic status. The stare diminishes, the movements characteristic of the disease disappear or diminish, the psychic status becomes normal or nearly so and there is usually a drop in the basal metabolic rate. This procedure may therefore be used as a diagnostic measure with a considerable degree of success provided sufficiently accurate observations of the patient's physiologic status and basal metabolic rates are made before instituting the administration of iodine.

Treatment—Until the cause of the disease is discovered and a specific therapeutic agent is found to combat the cause it is apparent that in the light of present knowledge the only rational method of attack consists in the employment of measures to reduce the activity of the thyroid gland supplemented by supportive and protective measures designed to eliminate such predisposing etiologic factors as overwork, mental and emotional stresses, infections and the like.

The measures most commonly employed in the endeavor to reduce the activity of exophthalmic goiter are (1) administration of iodine, (2) irradiation and (3) operation (Fig. 115) and (4) to these must be added treatment with thiouracil. Through the observations of many investigators, notably

Marine, Broders, Rienhoff, Cattell and others, it has been demonstrated that marked involutional changes occur in the hyperplastic and hypertrophic gland of exophthalmic goiter in the great majority of instances following the administration of iodine for a period of ten days or longer. Concomitant with these structural changes in the gland, there is usually diminution in the severity of the disease, as evidenced by amelioration of all the symptoms and reduction in the basal metabolic rate. Occasionally, if the patient has a very small goiter and is seen early in the course of the disease, his condition may be completely and permanently controlled by the administration of iodine. However, clinical experience has

The Mackenzies and Astwood, by studying the goitrogenic effects of various drugs, confirmed the finding that depression of thyroid function and hypertrophy of thyroid parenchyma followed administration of sulfonamides and drugs related to thiourea. Astwood treated exophthalmic goiter with thiourea and thiouracil and found that the basal metabolic rate fell to normal and that the symptoms and signs of the disease disappeared. This brilliant work constitutes an important advance in the study of thyroid function and provides a method of medical treatment of hyperthyroidism which may become extremely important. Some undesirable reactions have occurred after the use of thiouracil: Agranulocytosis, febrile reac-

Fig. 115.—A patient with an exophthalmic goiter. a, Before operation, b, after operation.

demonstrated that the maximal effect of iodine is commonly obtained within from seven to twenty days, and after this there is little hope that prolonged treatment will control the disease in the vast majority of cases.

Employment of irradiation in the treatment of exophthalmic goiter is based on the conception that the hypertrophic parenchymatous cells of the thyroid gland are peculiarly radio-sensitive, while the normal cells are radioresistant. Although experimental proof is lacking that involutional changes occur in the gland after irradiation, many advocates of this form of treatment have claimed good results from its employment. With few exceptions these claims have not been supported by sufficient factual data.

tions with or without a skin rash, and transient edema with elevation of the plasma chlorides and depression of the carbon dioxide-combining power of the plasma have occurred in some cases. The reported reactions have rarely resulted seriously, but obviously a drug which may produce such reactions must be carefully studied in a large series of cases before it can be widely used with safety. At the present time, patients taking thiouracil should be kept under careful and constant observation during the period of treatment. The ultimate place of this drug in the treatment of thyrotoxicosis has not been established definitely, but it seems likely that one important field of usefulness will be the preparation for surgical treatment of those patients who, because of

the severity of hyperthyroidism are poor surgical risks. When thiouracil is used to prepare patients for thyroidectomy it is desirable also to administer iodine for some days immediately before the operation.

Today the opinion prevails among those most experienced with the disease and its management that subtotal thyroidectomy is the treatment of choice for it most rapidly and most safely restores the patient to a state of economic efficiency and involves least likelihood of relapse. Spence permits only a limited discussion of the principles of management which can best be considered under three headings: (1) preoperative preparation, (2) criteria of operability and (3) operative principles.

Preoperative Treatment—In 1922 H. S. Plummer established the value of iodine in the treatment of exophthalmic goiter. In the uncomplicated case of exophthalmic goiter of moderate severity administration of 10 minims of compound solution of iodine three times daily for a period of from eight to ten days will bring about sufficient improvement to allow partial thyroidectomy to be performed with minimal risk and to abolish all fear of postoperative crisis. Patients who have exophthalmic goiter of more than average severity should be given iodine for longer periods and it has seemed advisable to hold those patients who have begun treatment during a crisis for a period of at least a few weeks on a regimen of iodine before consideration of operation in order that the profound physiologic disturbances incident to the crisis may have an opportunity to correct themselves during the period of general improvement. Cessation of treatment with iodine if a patient has exophthalmic goiter may result in the rapid development of a crisis. Although the basal metabolic rate usually drops during the period of administration of iodine this is not essential to improvement of the patient's physiologic status. Thiouracil or some other related drug may play an important part in the preoperative treatment in certain cases.

In order to maintain nutrition and to overcome the depletion of glycogen a liberal diet is advisable. Boothby and Sandiford have shown that such a diet will also keep the patient who has exophthalmic goiter in nitrogen balance. Often 2000 calories a day

are taken readily. The intake of fluid is also kept at a high level. During the period of preparation for operation it is important that the patient obtain adequate rest but he should not be continuously confined to bed. Evidence is accumulating which suggests that because of relative vitamin deficiency especially of vitamins A and B the addition of large amounts of these substances to the diet may be of value in some cases.

Complications Sometimes Encountered in the Preoperative Treatment—When exophthalmic goiter is complicated by other diseases the treatment of which is surgical treatment of the goiter usually should take precedence. Certain conditions which usually are treated medically also require attention.

1 **Diabetes**—Fitz Wilder and others have demonstrated the marked increase in severity of diabetes that may occur with the development of hyperthyroidism. Usually there is a considerable increase in the amount of insulin required. During the period of preoperative preparation it seems desirable from the standpoint of general nutrition as well as for restitution of depleted stores of glycogen and because of possible damage to the liver to give the patient who has diabetes and exophthalmic goiter a diet containing from 75 to 100 per cent more calories than the patient's basal diet and to give adequate amounts of insulin to control the glycosuria.

2 **Cardiac Decompensation**—Because Plummer showed that digitalis might have deleterious effects on a hyperthyroid patient this drug should be given only in small dose and with great caution. Fortunately other methods of treatment have proved so successful in relieving these patients of cardiac decompensation that digitalis is needed only rarely. In many cases rest in bed and the administration of iodine will result in rapid improvement in the cardiac condition and further treatment may not be necessary. When this treatment is not sufficient the mercurial diuretics usually will suffice to rid the patient of edema. Control of hyperthyroidism by thiouracil may result in marked improvement in the circulatory system. This drug may be of especial value in the preoperative treatment of such patients.

Criteria of Operability—When is it safe to operate and what procedure should be employed? On the proper solution of these two questions rests in a large degree the success of treatment. Obviously hard and fast rules of treatment cannot be applicable to all patients and each case must be judged by itself. In the final analysis accuracy of estimating the risk of operation to a patient who has an exophthalmic goiter is largely dependent on the experience of the surgeon. Always he should be cognizant of the fact that in an operation on a patient who has exophthalmic goiter there are three additional risks which are absent or uncommon if the patient has goiter unassociated with hyperthyroidism. These dangers are (1) the postoperative development of an acute hyperthyroid reaction especially likely to occur if the patient has severe hyperthyroidism, (2) the development of pulmonary infections commonly seen if the patient is markedly debilitated consequent to a recent crisis of the disease or to long continued hyperthyroidism and (3) hepatic insufficiency consequent to long continued hyperthyroidism. By adequate preoperative management these complications usually can be avoided.

In an uncomplicated case of exophthalmic goiter of average severity the administration of iodine for eight to ten days is usually sufficient preparation. The time necessary for iodine treatment is longer than this in children and in adults who have been recently in the crisis of the disease. It is desirable that the patient be gaining in weight and that the basal metabolic rate be dropping at the time of operation but in some instances these improvements cannot be achieved and operation will then entail a greater than normal risk. If the excessive nervousness and stimulation of the patient have subsided on preoperative treatment there is little or no risk of postoperative crisis. In cases in which there are complications or serious damage to vital organs preoperative treatment may be prolonged considerably to allow recovery from hepatic or cardiac damage. Only under extreme conditions need the preoperative treatment require more than three weeks.

However a small percentage of patients do not respond sufficiently to preoperative

treatment to become good risks and substitution of a lesser operative procedure such as ligation of the superior thyroid vessels or partial lobectomy at a diminished hazard may so improve the patient's condition that later subtotal thyroidectomy may be performed safely. Thionin with the subsequent addition of iodine may afford sufficiently effective preparation so that ligation of vessels or hemithyroidectomy may become unnecessary in such cases.

Operative Principles—The basic principles of the operation of partial thyroidectomy consist of (1) removal of a sufficient amount of the abnormal thyroid gland (commonly from 70 to 90 per cent of the whole) (2) preservation of thyroid tissue sufficient to maintain adequate function (usually equivalent to from one sixth to one third of a lobe of normal size) (3) control of bleeding (4) avoidance of sepsis and injury to adjacent structures and (5) attainment of a satisfactory cosmetic effect. The most common technical complications of the operation are secondary bleeding and injury of a recurrent laryngeal nerve. Fortunately both errors are avoidable provided the surgeon is constantly on the alert and plans the operative technique so as to afford maximal protection against their occurrence. If the posteromedial portion of the lobe is preserved without exposure of the lateral wall of the trachea this mass of tissue will serve as a protective barrier between the operative field and the nerve and seldom will injury of the nerve occur (Fig 186). Unless the operation consists of a needlessly radical removal of most of the thyroid tissue the development of postoperative parathyroid tetany is an exceedingly rare complication of primary operation on the thyroid gland. It is practically limited to operations for recurrent goiter. In these cases the threshold of safety is often reduced because of removal of one or more parathyroid glands in the first operation. In an operation on a patient who has a recurrent goiter it is wise for the surgeon to assume that all but one of the parathyroid glands were removed at the first operation and accordingly to preserve a generous portion of the posterior and lateral capsules to avoid injury to the remaining glandules.

Prognosis—The most important factor

which influences the prognosis in exophthalmic goiter operations is the presence of secondary complications of the disease notably the degenerative changes of the various organs such as the heart liver and muscles. Development of these changes is largely dependent on the duration and intensity of the disease. Following adequate preoperative preparation with iodine an operative mortality of 1 per cent or lower has been reported by several authors. Following subtotal thyroidectomy the basal metabolic rate ordinarily drops to the normal level within from two to four weeks with associated abatement of symptoms. By far the greater majority of these patients have returned to normal health within a period of from six to twelve months. If the disease is

wound is especially prone to occur after operations for the resection of the thyroid gland. Two facts in particular account for the tendency to bleed: (1) the extreme vascularity of the gland and (2) the fact that the remnant of the resected gland cannot be immobilized because of its attachment to the trachea. The seriousness of this complication usually is due not to the volume of blood lost but to suffocation and impairment of cardiac action resulting from compression of structures in the neck and upper mediastinum.

Bleeding commonly occurs within twelve hours (at most twenty-four hours) after operation and is manifested by swelling of the neck causing the patient to complain of tightness of the bandage, the development

Fig. 116—Cross section of (a) an exophthalmic goiter and (a') an adenomatous goiter showing the position and relative amount of the gland tissue preserved (shaded areas) in a subtotal thyroidectomy. b and b' show the reconstruction of the remnants of the glands into a more normal shape.

completely and permanently controlled early in its course disability is not likely to ensue. In a small number probably less than 5 per cent of cases in which partial thyroidectomy has been performed either manifestations of the disease are incompletely controlled or at some later date the symptoms and signs of exophthalmic goiter return.

Treatment of Complications after Thyroidectomy—The complications after partial thyroidectomy, the results of a technical error are limited for the most part to three: that is postoperative hemorrhage, injury to the recurrent laryngeal nerve or nerves and parathyroid insufficiency.

1. *Postoperative Hemorrhage*—Unskillful care is observed in obtaining accurate hemostasis, serious bleeding from the

of respiratory difficulty or stridor, a change in the voice (guttural) and cyanosis. After removal of the bandage the swollen neck usually makes the diagnosis obvious but occasionally among patients who have heavy cervical muscles there may be no apparent swelling. However the diagnosis should be suspected because of the increased firmness when the neck is palpated. Whenever this complication is suspected the patient should be returned immediately to the operating room, the wound reopened, the clot evacuated and the bleeding vessels ligated. If general anesthesia is contemplated the anesthetic agent should not be administered until after removal of the obstructing clots.

2. *Respiratory Stridor*—Among the causes of this complication the following may be

listed paralysis of one or both vocal cords hemorrhage into the wound tetany collapse of the trachea and edema of the glottis. However by far the most common is paralysis of the vocal cords incident to operative trauma of the recurrent laryngeal nerve. Injury to the nerve usually results in the fixation of the homolateral cord in the midline position thus narrowing the rima glottidis by half. In most instances this complication is unattended by serious stridor but in some cases associated with marked edema of the glottis serious respiratory difficulty may develop. Bilateral injury of recurrent nerves with the fixation of both cords in the midline position always is attended by serious stridor and usually requires tracheotomy for its relief. In rare instances gradual paralysis of both vocal cords may develop twenty-four to forty-eight hours after partial thyroidectomy when no injury has occurred directly to the recurrent laryngeal nerves and when both cords have moved normally after completion of the operation. This is a temporary paresis persisting for two to five days and probably results from edema and swelling of the nerves. Early administration of 50 to 60 per cent oxygen or of 90 to 40 per cent oxygen in helium may avert the necessity of tracheotomy. However if this does not relieve the labored respiratory efforts promptly, tracheotomy should not be delayed.

For the relief of partial respiratory obstruction the result of bilateral paralysis of the vocal cord among patients who have survived the operation of thyroidectomy King has devised an operation to widen the space between the two fixed vocal cords by the dislocation and lateral fixation of one of the arytenoid cartilages. This has proved to be successful in relief of dyspnea with only impairment of the speaking voice.

3 Parathyroid Insufficiency.—This is fortunately a rare complication but one which is frequently unrecognized unless looked for. Numbness of face or hands is usually the earliest symptom. Difficulty in focusing the eyes generalized weakness or respiratory stridor may be the only presenting symptom the latter occurring most frequently when one vocal cord is paralyzed. Carpopedal spasm or generalized convul-

sions usually occur only after the condition has existed for days. Chvostek's and Trousseau's signs are nearly pathognomonic. The concentration of calcium in the blood is lowered and that of inorganic phosphates increased. Prompt and persistent treatment preferably with calcium lactate in 4 Gm doses dissolved in very hot water and administered orally or in case of necessity with solution of calcium gluconate or chloride administered intravenously will give rapid control. In most cases the condition is temporary. However when it is prolonged or permanent the use of dihydrotachysterol and calcium will control even the most severe parathyroid insufficiency. Dihydrotachysterol (Holtz Gissel and Rossmann) usually is given in doses of 2 to 3 cc orally weekly. Supplementing it with calcium lactate or gluconate reduces the amount of dihydrotachysterol needed. Determination of the concentration of calcium in the blood should be made occasionally as toxic effects and hypercalcemia may occur in the treatment of some persons with very small doses of dihydrotachysterol. Cataracts and symmetrical cerebral calcifications may occur in cases of parathyroid insufficiency of long duration in which treatment has not been given. Parathyroid hormone also may be used in the treatment of this condition.

Recurrent Exophthalmic Goiter.—Exophthalmic goiter recurs or persists probably in those cases in which the cause of the disease is present with greatest intensity or persistence. The amount of thyroid tissue left after adequate resection is not the major factor which determines the recurrence of the disease. Enlargement of the thyroid may or may not occur. The factors which determine the enlargement of the gland are no more known than is the cause of the disease. All the manifestations of the disease may appear during a recurrence and the diagnostic problems are the same as they are in cases of primary exophthalmic goiter in which operation has not been performed. The treatment also is identical with the treatment of patients who have not been operated on except that in an appreciable number of cases satisfactory control can be achieved by the administration of iodine alone. Such control has been reported from the Mayo Clinic in 25 per cent of a series

of 468 cases in which exophthalmic goiter recurred. Recurrences have occurred less frequently in our cases since we have routinely given iodine constantly for a year after thyroidectomy.

Marked progressive exophthalmos with chemosis occurs very rarely among patients who have undergone partial thyroidectomy for exophthalmic goiter. According to Naffziger this condition is attributable to enormous swelling and degeneration of the intra-orbital muscles and relief is obtained by an operation for decompression of the orbit. Prolonged administration of iodine and of desiccated thyroid in those cases in which the basal metabolic rate is lowered seems to have been of value in some instances. Roentgen treatments to the orbits as described by Ruedemann, Ginsburg and others have been followed by subsidence of edema and exophthalmos in some cases. More patients must be treated before definite evaluation of any method of treatment can be made as in some instances rapid spontaneous remission may occur.

THYROIDITIS

In this discussion the term 'thyroiditis' is used to designate an inflammatory process involving the thyroid gland irrespective of the status of the gland before the onset of the inflammatory process.

Acute Thyroiditis.—Acute thyroiditis, a relatively rare condition, may run a self-limited course of from five to ten days and then may completely subside or suppuration and formation of abscess may ensue. Commonly the process is limited to one lobe but occasionally it may spread to involve the entire gland. In addition to increased vascularity and infiltration of the tissues by leukocytes and lymphocytes the histopathologic changes include hypertrophy and hyperplasia of the epithelium, the presence of foreign body giant cells and small follicular lumens containing a thin, poorly staining colloid and desquamated epithelial cells.

Symptoms.—The disease is commonly ushered in by chills followed by high fever and leukocytosis. In the milder forms however the entire course may be afebrile. Pain in the neck, usually not localized to the region of the thyroid gland, is diffuse, not only

throughout the cervical region but often is referred by way of the cervical nerves to the ear and occipital region. Pain is increased by movements of the head and on swallowing. The affected lobe of the gland enlarges is exquisitely tender and presents on palpation a firm or indurated consistence. Hoarseness occasionally is present and is attributable either to paralysis of a recurrent laryngeal nerve or to edema of the larynx. Dyspnea and cough may result from pressure of the swollen gland on the trachea. The disease not infrequently is associated with mild hyperthyroidism which may disappear with subsidence of the inflammation or may persist for a time afterward. In cases in which suppuration occurs and surgical drainage is not instituted the abscess may point in any direction. Usually however the pus burrows anteriorly through the skin but cases have been reported in which the abscess ruptured into the trachea or into the mediastinum with fatal outcome.

Prognosis.—In most cases of the non-suppurative form of thyroiditis the inflammation subsides spontaneously with complete resolution. In some cases the process may pass into chronic thyroiditis. The mortality is largely dependent on the primary or antecedent infectious process. Myxedema as a sequel of acute thyroiditis has been reported but is uncommon.

Treatment.—Application of heat to the cervical region will lessen pain and will aid in promoting resolution of the inflammatory process. Adequate surgical drainage should be instituted as soon as the formation of an abscess is suspected.

Chronic Non Specific Thyroiditis.—A relatively large number of goitrous glands are surgically resected which on histologic examination show unmistakable evidence of chronic inflammation of varying gradations. The cause of the inflammatory reaction in the gland is not known. The inflammatory changes are usually diffuse involving both lobes and are manifested chiefly by infiltration of the stroma by lymphocytes at times occurring in clumps of follicles with typical germ centers by the presence of plasma cells and by proliferation of the connective tissue stroma. Degeneration and desquamation of the epithelial elements may or may not be present. The presence of these changes in

the goitrous gland is of especial clinical importance because of the bearing it has on the ultimate prognosis following surgical resection of a goiter, especially an exophthalmic goiter. Myxedema as a sequela of subtotal thyroidectomy is practically confined to the cases in which the goitrous gland is also associated with thyroiditis. The more marked these changes are, the greater the likelihood of the development of myxedema. When these changes are recognized in the course of an operation, the risk of subsequent development of myxedema can be minimized by preserving more gland tissue than is normally preserved.

There are two forms of primary chronic non-specific thyroiditis of obscure origin

the patients, and the condition accounts for about 0.1 or 0.2 per cent of all cases of goiter in which operation has been performed in the Mayo Clinic. The disease is usually slow in its onset, which is marked by gradual enlargement of the thyroid gland and commonly by increasing dyspnea, which at times is alarming. As the disease progresses, the trachea and larynx become compressed, and edema of the larynx develops. Cases of any considerable duration are associated with evidence of diminished thyroid function, rarely, however, to the extent of the development of myxedema.

The gland is bilaterally enlarged, pre-ent- ing on palpation a very firm or hard tumor, which may be partially fixed to the sur-

Fig. 117—*a*, Diffuse chronic thyroiditis (woody type); *b*, diffuse carcinoma of the thyroid gland showing cord-like arrangement

which are commonly considered to be pathologic entities rather than advanced stages of the inflammatory process above described: (1) woody thyroiditis or Riedel's struma and (2) struma lymphomatosa (Hashimoto). Both of these processes may be superimposed on a previously goitrous gland, but more often on a non-goitrous gland.

Woody Thyroiditis or Riedel's "Eisenharte Strumitis".—This is a comparatively rare disease of the thyroid gland. Pathologically, chronic progressive sclerosis of extremely dense character involves not only the entire gland but frequently the adjacent structures as well (Fig. 117. *a*). Its occurrence is rare, females predominate among

rounding structures. Because of the infiltrating nature of the process, the borders of the tumor are often completely obliterated, however, unless the disease is superimposed on a goitrous gland, its surface usually remains smooth rather than nodular. It can be readily appreciated that the resemblance of this disease to advanced cancer of the thyroid gland may be so close that the two are clinically indistinguishable. The bilateral involvement, the smooth surface, the stony hardness and the absence of enlarged cervical nodes are more suggestive of Riedel's struma than of cancer, but commonly removal of a portion of the tumor for microscopic study offers the only means of making a definite diagnosis.

In cases in which treatment has not been given the process is rarely regressive usually progressive and occasionally stationary Following partial resection of the gland there is commonly striking regression with relief of all symptoms of pressure

Surgical exploration of the tumor is indicated in practically all cases for the dual purpose of establishing the diagnosis and of relieving or preventing tracheal compression In most instances the operation indicated is bilateral partial resection of the thyroid gland with removal of the isthmus a generous portion of each lobe is preserved In those cases in which the process has infiltrated into surrounding structures the hazard of resecting a lateral lobe may be prohibitive In such instances the trachea may be decompressed by removal of the isthmus and this will be accompanied by relief of dyspnea and sometimes will be followed by marked decrease in the size of the tumor In about 50 per cent of the cases in which operation was performed at the Mayo Clinic hypothyroidism or myxedema subsequently developed

Struma Lymphomatosa (Hashimoto) or Lymphadenoid Goiter (Williamson and Pearce)—This is a comparatively rare disease of unknown cause characterized by moderate enlargement of the thyroid gland the result of abundant and diffuse lymphoid infiltration which ultimately destroys or seriously impairs its function Whether or not lymphoid infiltration is an inflammatory process is not definitely known The condition is apparently analogous to a rare disease of the salivary and lacrimal glands described by Mikulicz in which these glands enlarge as a result of diffuse lymphoid infiltration It is commonly mistaken for colloid or adenomatous goiter and occasionally for carcinoma As the disease progresses myxedema is prone to develop whether the thyroid is resected or not Roentgen treatment has given good results in some hands Surgical treatment may be advisable to exclude the possibility of cancer or to relieve symptoms of pressure

Specific or Granulomatous Thyroiditis—Cases of syphilis and actinomycosis of the thyroid gland have been reported but they are exceedingly rare Only one form will be considered at any considerable length

Tuberculous Thyroiditis—Proved tuberculosis of the thyroid gland is rarely seen In generalized miliary tuberculosis tubercles are occasionally found in the thyroid gland

Microscopic lesions resembling tubercles and containing giant cells are frequently found in the thyroid glands of patients presenting the clinical picture of exophthalmic goiter and occasionally in cases of nodular goiter In most of these cases *Mycobacterium tuberculosis* cannot be demonstrated in the tubercles or by inoculation of guinea pigs The giant cells in some instances have been shown to include bits of colloid The patients are usually free from demonstrable tuberculosis elsewhere The immediate and end results of subtotal thyroidectomy in these cases are as satisfactory as they are in cases of comparable goitrous lesions in which microscopic examination does not suggest tuberculosis It seems probable that most patients in this category do not have tuberculosis of the thyroid gland

MYXEDEMA

Myxedema is a constitutional disease resulting from partial or complete destruction of the thyroid gland and characterized by a low basal metabolic rate and edema of the tissues of the body This may occur spontaneously commonly as a result of an inflammatory process of low grade or the loss of function may follow operative removal of the gland

Clinical Consideration—The most characteristic changes in myxedema are produced by edema The typical facial appearance results from edema of the subcutaneous tissues with resultant loss of expression The voice is coarse and low pitched because of edema of the vocal cords The skin is dry and scaling Physical and mental activities are slowed Recovery of the peripheral tendon reflexes is slowed (Chaney)

The basal metabolic rate is low and the concentration of blood cholesterol is elevated Slight enlargement of the heart occurs frequently The T waves of the electrocardiogram are usually flattened or inverted and rarely other abnormalities are present such as prolongation of the P R interval Anemia is a frequent accompaniment of long standing myxedema The color in

dev is high and macrocytosis may be present. The gastric content frequently contains no free hydrochloric acid.

Treatment—The fundamental principle underlying the treatment of myxedema is deliverance to the body of a constant supply of thyroxin in quantities sufficient to maintain the basal metabolic rate at the individual normal level. This program necessitates administration of thyroid or thyroxin at regular intervals preferably daily and in constant amounts.

Not all patients who have low basal metabolic rates after thyroidectomy actually have thyroid deficiency. There are many people who normally have basal metabolic rates lower than the average and who do not give evidence of any of the changes which invariably appear in those persons known to be deficient in thyroid. The patients who have low basal metabolic rates without evidence of myxedema are often ansthenic and easily fatigable and ordinarily present complaints similar to those heard from patients who have so-called chronic nervous exhaustion.

CRETINISM

Cretinism occurs sporadically in this country. Patients afflicted with cretinism having been deficient in thyroid from birth or during intrauterine life ordinarily sustain injury to the central nervous system which is not overcome by administration of thyroid even though this may be instituted at an early age. The symptoms and signs are those of myxedema with the additional disturbances of development dependent on an insufficiency of thyroxine during the formative years of life.

MALIGNANT DYSPLASIA

The reported incidence of malignant disease of the thyroid gland varies in different communities; it is higher in goitrous regions than in non-goitrous regions. Wegelin gave the astonishingly high incidence in Berne of carcinoma of the thyroid gland in one in every 96 postmortem examinations whereas in Berlin it was one in 1033 and in the United States one in 928. Among patients operated on for goiter the frequency of carcinoma of the thyroid gland as compared with benign nodular goiter is about 2.5 to

3 per cent while as compared with all benign goiters the average is about 1 per cent. The disease is more frequent among females in the proportion of two to one. The age incidence of the disease corresponds closely with that of malignant disease of other organs. 69 per cent of the patients are within the fourth, fifth and sixth decades of life. It is worthy of emphasis that about 3 per cent of the patients are in the first and second decades of life. From the histories of patients who have malignant disease of the thyroid gland evidence appears conclusive that in a large percentage of the cases the malignant process develops on the basis of a pre-existing benign goiter. Occasionally, however, it develops in a nongoitrous gland and very rarely in the hypertrophic gland of exophthalmic goiter.

There is widespread variation in the structural and biologic characteristics of malignant thyroid tumors and because of a close although not constant relationship between the clinical course of the disease and the pathologic features of the growth a classification of the malignant tumors based on this relationship is desirable. The following clinicopathologic classification of primary malignant tumors of the thyroid gland has proved satisfactory.

- 1 Papillary adenocarcinoma
- 2 Adenocarcinoma in a fetal adenoma (malignant adenoma or struma proliferans)
- 3 Diffuse adenocarcinoma
- 4 Epithelioma
- 5 Sarcoma

Tumors of epithelial origin constitute an overwhelming proportion of the malignant diseases of the thyroid gland about 98 per cent. Of these about 70 per cent are of the relatively low grades of malignancy (1 and 2). The diagnosis of malignant disease of the thyroid gland just like that of malignant disease elsewhere in the body is based on the presence of anaplasia or cellular differentiation.

The Various Types of Malignant Growth—These will be taken up according to the classification just given.

Papillary Adenocarcinoma—Commonly this tumor has its origin in a pre-existing benign tumor but occasionally it is seen to arise in a non-goitrous gland. It is readily

distinguishable by its papilliferous structure. While this type of thyroid carcinoma is always of a low grade of malignancy, grade 1 or 2, it has a marked tendency to invade the lymph spaces and to spread to involve the cervical lymph nodes. The growth is very slowly progressive and in inoperable cases it usually will remain localized in the cervical region for many years. In a series of 267 cases of malignant disease of the thyroid gland reported from the Mayo Clinic this type of tumor constituted 30 per cent.

Occasionally papillary adenocarcinomas of the thyroid structure occur as single or multiple nodules in the neck separated from the thyroid gland. They are found lateral to the gland above the superior pole along the course of the deep jugular vein or in the posterior cervical triangle. Usually they are partially cystic and of a dark color. The origin of these tumors is usually attributed to misplaced rests of thyroid tissue. The remnant of the lateral primordial structure. There is more evidence, however, to indicate that they are secondary to a primary

spindle-shaped or giant cells may simulate the picture of sarcoma. Metastasis occurs by way of the lymph or blood stream or both. The acute fulminating malignant epithelial growths of the thyroid gland are represented by this type. Diffuse adenocarcinoma represented 27 per cent of the previously mentioned series.

Squamous Epithelioma—These tumors of the thyroid gland may arise directly by metaplasia of its epithelium or secondly from extension of epithelioma of the esophagus, trachea or thyroglossal duct. This type of growth is extremely rare and exceedingly malignant. The prognosis is grave.

Sarcoma—This is of very rare occurrence in the thyroid gland. It constitutes probably not more than 1 per cent of all malignant growths of this structure.

Metastasis—Distant disseminations of malignant epithelial growths of the thyroid gland may occur as single or multiple nodules involving different organs. The most common sites are the regional lymph nodes, lungs, mediastinum and bones.

Clinical Considerations of Malignant Disease—Symptoms on which the diagnosis can be made definitely are usually not present until the malignant tumor has perforated the capsule of the gland and has invaded the surrounding structures. At this stage there is a hard, irregular, nodular tumor, often unilateral and fixed in its bed, with or without cervical involvement frequently associated with hoarseness and paralysis of a vocal cord. Horner's syndrome, a sense of pressure or pain in the neck, pain along the distribution of cervical nerves, dysphagia, dyspnea and loss of weight. Then and not until then can the diagnosis be made with any degree of accuracy. Unfortunately when the diagnosis is obvious the growth may have advanced beyond the reach of the surgeon.

Prior to the time when the malignant process has invaded contiguous structures, features which are suggestive of the diagnosis may or may not be present. The sudden development of a tumor in a non-glandular gland or rapid growth of an adenoma of long standing always should be looked on with serious misgivings. Unusual firmness of the tumor should arouse further suspicion. Evidence of early invasion sometimes can

be obtained by detecting diminished mobility of the tumor and by the development of hoarseness associated with paralysis of a vocal cord. Estimation of the basal metabolic rate is of no value as an aid in distinguishing benign from malignant tumors since there is no constancy of the basal metabolic rate in either condition. Unfortunately in many instances there are no features of early malignant tumors by which they may be distinguished clinically from benign tumors.

Treatment—The principles of treatment of malignant disease of the thyroid gland should be considered according to the stage of development of the disease that is consideration should be given to whether the case is operable or inoperable and to whether the growth is a benign adenoma that may be a precursor of a malignant tumor. Operability depends on the extent of local invasion of the primary lesion and on absence of distant metastasis. Tumors which are completely fixed to all the contiguous structures should not be operated on for the prospects of benefiting the patient under these circumstances are not commensurate with the hazard involved in extirpating the growth. However if mobility is merely restricted thus suggesting perforation at only one point operation should be undertaken for not infrequently the tumor can be removed in its entirety. When the tumor is partially fixed and the cervical nodes are involved extensive surgical removal of the primary growth together with dissection of the affected cervical nodes is often justifiable if the growth is of the papillary form whereas the operation is only futile if the growth is of one of the more highly malignant forms.

The treatment indicated for encapsulated malignant growths which may be represented by any one of the three common epithelial neoplasms is wide surgical removal supplemented by postoperative irradiation by radium and roentgen rays. This form of treatment will produce satisfactory results as the more radical operation of total thyroidectomy. Since malignant growths of the thyroid gland are for the most part radiosensitive occasionally surprisingly good results have been obtained

in inoperable cases by treatment with radium and roentgen rays.

Adenoma as a Precursor of Malignant Growths—From the fact that a large percentage of all malignant tumors of the thyroid gland develop in a pre-existing benign nodular goiter, it is obvious that retention of a nodular goiter subjects the patient to a certain potential risk of developing malignant growth. This risk does not exceed 1 to 2 per cent but when added to the other potential risks of a neglected nodular goiter that is development of hyperthyroidism and development of symptoms of pressure consequent to growth of the goiter it is apparent that the danger of retaining the goiter is probably greater than the danger incident to its surgical removal.

Prognosis—Because of the difficulty of distinguishing by clinical methods a benign from a malignant tumor of the thyroid gland about 50 per cent of the patients who have carcinoma of the thyroid gland have an inoperable condition when they present themselves for treatment. Following irradiation a small percentage of these patients will live for five years or longer, for the most part these patients have a low grade papillary form of the disease. The average length of life following treatment is about twenty-one months. In operable cases the most important factors which influence prognosis are the type and grade of the neoplasm. In order from least malignant to most malignant tumors of the thyroid gland of malignant types may be named as follows: papillary adenocarcinoma, malignant adenoma, diffuse adenocarcinoma and sarcoma and squamous cell epithelioma. Almost without exception patients who have sarcoma or squamous cell epithelioma die within a year of operation whereas nearly 50 per cent of the patients who have other forms of neoplasm live five years or longer following surgical removal of the tumor.

ANOMALIES

Wegehn has classified development of anomalies of the thyroid gland in six groups: (1) complete aplasia (sporadic cretinism), (2) failure of descent of the thyroid anlage with heterotopia of the thyroid tissue at the root of the tongue, (3) partial aplasia

(4) simple hypoplasia (5) retention of the thyroglossal duct and (6) accessory glands as a result of aberrant thyroid tissue (lateral inferior and intratracheal forms)

Lingual Thyroid or Lingual Goiter.—When heterotopic thyroid tissue is present at the base of the tongue near the foramen cecum it is commonly referred to as a lingual thyroid or lingual goiter. This tumor may constitute all the thyroid tissue possessed by the individual or it may occur in association with a normally or imperfectly developed cervical thyroid gland. As a rule the condition is not recognized until adult life when growth of the tissue becomes manifest by the presence of a swelling at the root of the tongue. The symptoms of cough, dyspnea and dysphagia are dependent on the size of the tumor, which some times may reach that of a walnut or larger. Ulceration of the tumor is then not uncommon, resulting in alarming hemorrhage.

Treatment.—Since the lingual thyroid may represent all the thyroid gland and since its surgical removal is difficult because of its relative inaccessibility, an operation should not be undertaken unless the tumor produces definite symptoms. However, should symptoms develop to require treatment partial or complete excision of the tumor is indicated. The approach is through the mouth and to insure a free passageway for air during the course of the operation preliminary tracheal intubation has been recommended.

Thyroglossal Duct Cyst or Fistula.—[See section on *Thyroglossal Cysts and Fistulas*]

THE PARATHYROID GLANDS

ANATOMY AND PHYSIOLOGY

Anatomy.—The parathyroid glands first appear as definite structures in the staphylia and are present and so far as is known exert an analogous function in reptiles birds and mammals. They are developed from dorsocranial thickenings of the epithelium of the third and fourth branchial pouches in the embryo in mammals and accordingly are often intimately associated anatomically with the thymus which arises from ventral outgrowths of these same structures. In their further development the parathyroids become separated from the primitive gullet and in many animals are more or less completely enclosed within the lateral lobes of the thyroid which develop from the epithelium of the fifth branchial pouch. Commonly there are four glands two closely associated with each thyroid lobe and a varying number of islands or nodules of accessory parathyroid in the thymus or in the connective tissue in the anterior mediastinum along the trachea, arch of the aorta or pulmonary artery. In mammals the four glands weigh less than half a gram. They are made up of strands of epithelial cells supported by a reticulum of endothelial cells of varying size and shape and enclosed by a connective tissue capsule. Often there is no definite columnar arrangement the cells appearing in masses or clumps but sometimes there is follicle formation containing colloid the significance of which is unknown. The parenchyma consists of fairly large polygonal cells with deeply staining nuclei and poorly staining cytoplasm the chief cells and a smaller number of slightly smaller cells with granular deeply staining cytoplasm and small central nuclei the chromophile cells. The blood supply to the parathyroids is by way of the superior and inferior thyroid arteries and is very abundant. Nerves to the parathyroids accompanying the blood vessels have been described some of which terminate in the vessel walls but many of which penetrate between the epithelial cells forming nodular enlargements. The function of these nerves is unknown. Transplantations on experiments have demonstrated however that the parathyroids can function adequately in the absence of all nervous connections.

Physiology.—The parathyroids belong to the group of endocrine glands and perform their vital function by means of an internal secretion. An extract of the glands containing the specific hormone in fairly pure form was prepared by Hanson (1923) and Collip (1925) and is available in the market for clinical use. It is biologically standardized and is effective only on subcutaneous or slow intravenous injection. When the parathyroid glands are removed or destroyed by disease a syndrome known as parathyroid tetany develops in a few days and rapidly leads to death unless adequate therapy is instituted. The careful injection of potent parathyroid extracts will control these deficiency symptoms.

An intimate relation has been established between the function of the parathyroid glands and the metabolism of calcium and phosphorus. When the glands are removed or suddenly destroyed by disease the concentration of total calcium in the blood serum decreases the ionized calcium decreases, the inorganic phosphorus rises and the excretion of phosphorus in the urine is lessened. The administration of parathyroid extract corrects these alterations while excessive doses raise the serum calcium to very high levels, bring about the removal of calcium and phosphorus from the bones and accelerate the excretion of these substances in the urine and feces. Presumably under normal conditions the amount of parathyroid hormone liberated from the glands suffices to keep the level of serum calcium constant in spite of variables in the way of absorption from the alimentary tract and excretion or withdrawal in special cases such as pregnancy or lactation. In common with several of the other endocrine organs disturbances due to hypofunction and hyperfunction of the parathyroids are clearly recognized.

HYPOFUNCTION OF THE PARATHYROID GLANDS

Deficiency symptoms are seen most commonly in animals following experimental extirpation and in man as a result of accidental injury to the parathyroid glands in goiter operations. When all of the glands are removed or destroyed in man or the lower animals severe tetany ensues within

two or three days characterized by fibrillary tremors of the voluntary muscles intermittent attacks of tonic and clonic convulsions hyperpnea salivation severe depression and death Fortunately in man such an abrupt loss of all parathyroid tissue rarely occurs the functional deficiency is only partial and milder symptoms develop in some cases to be made manifest only under special conditions The cardinal symptom is increased irritability of the peripheral motor nerves so that they are more easily excited by electrical stimulation (Erb's sign) mechanical stimulation (Chvostek's sign) or asphyxia (Trousseau's sign) than are normal nerves Most patients never experience convulsions but complain of stiffness in various muscles especially those of the fingers legs face and neck and cramps in the extremities Spastic contractions in the fingers and toes may be seen which are aggravated by temporary circulatory occlusion

The most reliable sign of hypofunction of the parathyroid glands is the decreased concentration of the serum calcium from a normal of between 10 and 12 mg to between 8 and 6 mg or even lower and the elevation in the serum phosphorus It is probable that the hyperirritability of the motor nerves in this condition is due to the abrupt alteration in the concentration of the various ions in the blood and lymph and of these the decrease in calcium ions seems to be the most important One manifestation of the disturbed calcium metabolism is the lessened deposition of calcium in osteoid tissue so that fractures heal with difficulty and non union is frequent The frequent occurrence of bilateral entriets is one of the tragic consequences of parathyroid insufficiency and emphasizes the danger of indiscriminate surgical removal

The treatment of hypoparathyroidism is fortunately fairly adequate Acute cases may be controlled by subcutaneous injection of parathyroid extract (Collip) or intravenous injection of 5 per cent CaCl_2 solution or Ringer's solution (1500 cc) For continued treatment which is usually necessary it is best to place the patient on a meat free diet and give from 5 to 25 Gm of calcium lactate or gluconate and from 25 to 50 Gm of lactose daily by mouth Dihydroxyvitamin D₂ a synthetic product pro-

duced by irradiating ergosterol causes a long-continued rise in the blood calcium level when given by mouth and is a most useful drug for the treatment of chronic hypoparathyroidism It is available as a 0.2 per cent solution in oil and is given in doses of 1 to 3 cc daily Frequent estimations of the blood calcium content should be made with adjustment of the dosage

HYPERFUNCTION OF THE PARATHYROID GLANDS

Systemic symptoms due to the liberation into the blood of an abnormally large amount of the parathyroid hormone are seen most commonly when a parathyroid adenoma is present but may occasionally occur in generalized hyperplasia of all parathyroid tissue The adenoma may occur in any of the normal sites of the four glands but has also been found to involve accessory parathyroid tissue in the mediastinum and elsewhere The tumor is grossly an encapsulated soft lobulated yellowish gray mass which is composed of syncytium like groups of large cells containing large oval darkly stained nuclei with abundant pale granular cytoplasm and closely packed or arranged in small alveoli enclosing colloid The adenoma is usually too small to produce local symptoms but the general manifestations may be profound The disease is more common in females and is most frequent in the middle decade of life The onset is insidious and the course of the disease may extend over many years The symptoms are all referable to the influence of the excessive amounts of the hormone in removing calcium and phosphorus from the skeleton and causing their excretion in the urine Pain in the bones intensified by exercise and general bone tenderness are commonly seen X-ray examination of the skeleton reveals the characteristic changes of osteitis fibrosa cystica or von Recklinghausen's disease and this disease is now known to be due to hyperparathyroidism The principal changes are generalized decalcification of the skeleton with thinning of the cortex and trabeculae of the long bones the formation of multiple bone cysts and giant cell tumors or osteoclastomas and in late stages spontaneous fractures and deformities due to generalized softening of the

bones Polydipsia polyuria muscular weakness constipation loss of appetite and leukopenia are frequent symptoms. In about 30 per cent of the cases the excessive excretion of calcium and phosphate in the urine leads to the formation of calculi in the kidney pelvis and symptoms of renal colic or to the deposition of calcium phosphate in the kidney parenchyma with secondary contracture and renal insufficiency. This nephrocalcinosis has frequently led to the diagnosis of the disease. This is most dependably made by laboratory examinations which reveal hypercalcemia hypophosphatemia hypercalciuria hyperphosphaturia and a negative calcium balance.

Treatment of hyperparathyroidism consists in the discovery and removal of the responsible parathyroid adenoma. The surgeon must secure a bloodless field and be prepared to examine the usual sites of the glands and if necessary to enter the mediastinum. The removal of the adenoma may cause such an abrupt fall in the serum calcium content as to precipitate severe or fatal tetany. This should be guarded against by the adoption of the methods previously described for the treatment of hypoparathyroidism. Operations have been performed in about 125 cases of osteitis fibrosa cystica in which the laboratory and clinical findings of hyperparathyroidism were present. In about 80 per cent of these a parathyroid adenoma has been found and removed. The results have been for the most part strikingly beneficial. The blood calcium content has rapidly declined to its normal level and the increased excretion of calcium and phosphorus in the urine has ceased. The patients have gained in weight and strength and joint and bone pains and tenderness have disappeared. X-ray examination of the skeleton has revealed a progressive increase in density and the cystic spaces have become largely replaced by normal bone. In those cases in which a parathyroid adenoma was not found at operation and one or two of the normal glands were removed persistence or recurrence of symptoms has been the rule. In these it is probable that an adenoma was present probably associated with aberrant parathyroid tissue in the mediastinum or in the substance of the thyroid or elsewhere where its discovery presented great technical difficulties.

In a few instances generalized hyperplasia of all parathyroid tissue has been reported at operation and in these the extirpation of one or two of the enlarged glands has resulted in temporary improvement. The results however have not been as definite as those that follow the removal of the adenoma.

At present there is no good evidence that Paget's disease ankylosing spondylitis or osteomalacia or osteogenesis imperfecta is due to hyperparathyroidism and parathyroidectomy is not indicated in these diseases.

ABNORMALITIES OF THE THYMUS

Many interesting studies have been performed in an attempt to determine the function of the thymus. The early observations of a number of investigators indicated that the thymus is concerned with calcium metabolism and with the growth of bone. Subsequent studies by Park and McClure showed that the previous findings were due to inadequate diet and confinement of the animals rather than to thymectomy. The evidence concerning the relationship of the thymus and the gonads is controversial and will not be discussed here. Lohr and Rowntree found that thymectomy results in a retardation of growth in successive generations of rats commencing in the second generation. The interesting observation was made by Gubernatsek that the feeding of thymus tissue to tadpoles was followed by an increase in the rate of growth and by retarded metamorphosis. Asher and Rown-

tree found that multiple injections of thymic extracts influence the rate of growth of rats. The most amazing observations are those of Adler who states that the multiple injection of thymic extract or the implantation of thymic tissue into dogs causes a syndrome resembling myasthenia gravis in the human.

Despite the large number of clinical and experimental observations the function of the thymus is unknown. From the clinical viewpoint the most suggestive evidence that the thymus has a function arises from the frequent association of benign tumors of the thymus and myasthenia gravis and from the relationship of enlargement of the thymus and thyrotoxicosis.

HYPERPLASIA

Normally the thymus increases in size up to the age of two or three years and usually remains at approximately this size until the twelfth year. Following this it decreases slowly in size and may disappear entirely.

Hyperplasia of the thymus may occur particularly in children and may result in respiratory difficulty. This does not occur as frequently as was previously believed to be the case. Thymectomy has been employed successfully for the relief of dyspnea but the operation has been replaced by radiation therapy with equally good results.

Little is known about status thymicolymphaticus in which there is an enlarged thymus and hypertrophy of all the lymphatic tissues. In fact many deny the existence of such a clinical entity. At any rate it seems likely that too many otherwise inexplicable anesthetic deaths have been ascribed to status thymicolymphaticus. In this connection it should be remembered that prolonged illnesses are accompanied by a decrease in the size of the thymus and that the thymus of a previously well child who dies suddenly is normally rather large.

MALIGNANT TUMORS

The majority of thymic tumors are malignant. It is difficult to establish the thymic origin of a tumor unless Hassall's corpuscles are found on microscopic examination. Irving has given an excellent description of the variations in structure which may be encountered in thymic tumors. He states

that a full survey of the structural variations reveal at one extreme a mixed process involving lymphocytes and reticulum cells with giant plasma and eosinophil cells producing a structure nearly identical with Hodgkin's granuloma and at the other extreme nearly pure tumors of rounded or polyhedral reticulum cells namely lymphosarcoma and carcinoma. More than 200 malignant tumors of the thymus have been reported in the literature.

The clinical picture presented by patients with malignant thymic tumors resembles that of patients with other malignant tumors of the anterior mediastinum. The symptoms in the main are those of progressive mediastinal compression. Pleural effusion, tachycardia and anemia may be present.

The diagnosis is usually not made until the mass reaches a rather large size. The symptoms of compression the physical signs of an anterior mediastinal mass and the x-ray shadow should suggest the diagnosis.

Treatment is unsatisfactory and patients rarely live more than a few months after the lesion is discovered. Roentgenotherapy is preferable to an attempt at extirpation by surgical means.

BENIGN TUMORS

Benign tumors of the thymus are rare and most of those that have been reported were in patients with myasthenia gravis. Bell stated that the thymic tumors occurring in such patients form a distinct group. He collected from the literature of 1901-1917 reports of 56 cases of myasthenia gravis in which autopsies or operations had been performed and in 27 of these cases abnormalities of the thymus were exhibited. The corresponding figures in 1939 were 57 abnormalities of the thymus in 110 operations or autopsies upon patients with myasthenia gravis (Blalock, Mason, Morgan and Riven). The frequent association of benign tumors or hyperplasia and myasthenia would appear to be more than a coincidence.

If a benign tumor reaches a large size which is usually not the case the symptoms are those of progressive mediastinal compression.

The diagnosis of a benign tumor is usually made as a result of suspecting such a

lesion in association with myasthenia gravis. The tumor is usually demonstrated best on a lateral roentgenogram.

Remissions in myasthenia gravis are not uncommon and it is difficult to judge the effects of therapy. Surgical extirpation of a benign thymic tumor has been followed by marked improvement in most cases in which this form of therapy has been used.

The effects of total thymectomy in the absence of a thymic tumor are less definite. This form of therapy was suggested by Blacklock, Harvey, Ford and Ilienthal in 1911. There has been sufficient improvement (Blacklock, Carson and Keynes) in most of the patients to warrant this operation on those with severe myasthenia gravis.

THE ISLANDS OF LANGERHANS

HYPOGLYCEMIA

After Minkowski established the fact that total extirpation of the pancreas in the experimental animal is associated with glycosuria, evidence began to accumulate pointing to the presence of an internal secretion produced by this organ and having to do with carbohydrate metabolism. Later Opie showed that the elaboration of this secretion comes from the islands of Langerhans. Bensley demonstrated that the beta cells of the islands have the particular function of secreting a substance concerned with carbohydrate breakdown. This sub-

stance was subsequently isolated by Bunting and Best and given the name of insulin. Insulin lowers the level of sugar in the blood.

Symptomatology—With the appearance of widespread clinical use of insulin, reports of symptoms of overdosage began to appear. The most remarkable effect of such an overdose is a very noticeable lowering of the amount of sugar in the blood. The acute hypoglycemia in turn is associated with phenomena such as malaise, lassitude, inability to perform mental or physical work, trembling and sweating, alternate pallor and flushing of the face, a sensation of hunger which sometimes may be extreme, mental confusion resembling alcohol intoxication, epileptoid convulsions, coma, and even death. In 1924 Scule Harris demonstrated the presence of hypoglycemia appearing spontaneously and associated with the identical symptomatology as that described when too much insulin is injected into the blood stream. He accordingly suggested that a condition of hyperinsulinism or dysinsulinism can occur spontaneously.

The first positive evidence that such a condition can be associated with an organic lesion of the pancreas was presented by Wilder, Allan, Power and Robertson in 1927. Their report concerned a man who had many of the symptoms mentioned together with a low blood sugar level. At operation there was found an inoperable carcinoma of the islet tissue with metastases to the liver. Their demonstration of the presence of insulin in the metastases from the tumor was a most important contribution. Shortly after the publication of this observation, other examples of tumors of the islet tissue differing somewhat in type began to appear. Very rapidly a considerable amount of clinical and experimental data related to this subject was amassed. So extensive is this literature that a careful detailed review would require a monograph of considerable size. The surgical removal of the tumor of the islet tissue with dramatic relief of symptoms has been reported well over a hundred times in the literature, and these reports probably represent only a small number of the operations that have been done.²

Pathology—For the most part the tumors which have been removed have been

small measuring not more than 1 or 2 cm in diameter although in one case a tumor which weighed 500 Gm was successfully removed. At operation the tumor usually appears as a small slightly excretory elevation from the surface of the pancreas. It is also somewhat firmer than the substance of the gland and may be present in any part of the organ. In some cases it has been well encapsulated while in others it has been necessary to excise normal pancreatic tissue around the tumor in order to remove it completely. Microscopically these tumors have been composed of cells showing a marked tendency to resemble the beta type of cell and the symptoms of hypoglycemia are generally in direct proportion in their severity to the extent of this differentiation into the insulin producing cells. Hyalinization and degeneration also are occasionally seen and appear to be related to the delicate but extensive blood vessels which these tumors possess.

Microscopically encapsulation for the most part is absent or incomplete. There is a definite tendency for the tumor cells to penetrate through the adventitious fibrous capsular tissue and this has led to considerable difference of opinion as to what constitutes adenoma and what is carcinoma. Those tumors that have not invaded blood vessels and have not extended outside of the pancreas have generally responded as benign lesions and for practical purposes such evidences of extension may be used as a point of differentiation between adenoma and carcinoma. In carcinoma as in adenoma the severity of the hypoglycemic symptoms seems to be related more to the amount of differentiation toward the beta cells present in the cancer than to the size or the extent of the lesion. When these tumors metastasize the most common site is the liver. Invasion into the regional lymph nodes and into the contiguous tissues about the pancreas has occurred but is extremely rare. Multiple benign tumors may occur and the entire pancreas should be examined for such a situation. The genesis of the island cell tumor is probably from the duct cell. The epithelium of the duct is multipotent capable of forming either acinar or island tissue while a mature beta cell probably possesses a poor capacity for regeneration. Furthermore

there is a great tendency to the resemblance of duct epithelium in many of the cells of the tumors. Ducts have been shown to be present in some of these lesions. It is questionable if true acinar cells are ever found in these island tumors just as island tissue is difficult to demonstrate in acinar cancers.

Occasionally a patient presenting symptoms of hypoglycemia has been operated upon and no tumor found. Many of these patients have been thought to have had a diffuse hyperplasia of the island tissue. Because of the normal variation in size and number of islands such statements must be received with caution. An island may normally vary in size from a single cell to a mass as large as 300 or more microns in diameter. Because of such unusual variations therefore any conception of the production of hypoglycemia as a result of increase in the amount of normal island tissue is most difficult to prove. For a more extensive discussion of the pathology of tumors of the island cells reference may be made to the papers on this subject by O'Leary and Womack,⁴ Duff and Gomori.⁶

Diagnosis.—The diagnosis of tumor of the island tissue of the pancreas may at times be extremely difficult to make with certainty. Usually however this is not so. Whenever one is confronted with a patient whose fasting blood sugar level is persistently low (50 mg per cent or less) the presence of an adenoma should be strongly suspected. This suspicion will be stronger if the patient also has a history of mental confusion or epileptiform convulsions before breakfast which are relieved by the ingestion of sweet food or drinks. But similar symptoms have been found associated with pituitary tumors and occasionally even with adrenal tumors. Again it is essential that a distinction be made between a chronic and an acute condition of hypoglycemia. After excessive overindulgence in carbohydrate food the withdrawal of carbohydrates will sometimes lead to the production of acute hypoglycemia and its train of characteristic symptoms which may continue for more than twenty-four hours. This condition is particularly prevalent among children and has been noted frequently at the St. Louis Children's Hospital. The most probable explanation is that the excessive ingestion of

carbohydrate food calls forth an excessive production of insulin which is maintained for several hours after the excessive supply of sugar has been stopped. The condition is therefore analogous to insulin shock produced by artificial injection of an overdose of insulin. Obviously there is no indication for surgical exploration of the pancreas in such cases.

In the establishment of the diagnosis of a tumor the patient must present certain symptoms usually found associated with hypoglycemia and during the time these symptoms are present the patient must be shown to have hypoglycemia. Following the administration of glucose these symptoms must disappear immediately. If the symptoms ever appear with a relatively normal blood sugar level or if the low blood sugar level is inconstant they probably are not due to hypoglycemia and under such circumstances removal of a portion of the pancreas is of little value. If characteristic hypoglycemic symptoms can ever be shown to exist with a normal blood sugar level the resection of a portion of the pancreas so that there will be a constant normal blood sugar will probably not relieve the symptoms.

Treatment—When a tumor can be demonstrated to be present the most satisfactory treatment is extirpation. Adequate exposure of the pancreas may be obtained through either the gastrohepatic omentum or the gastrosplenic omentum depending upon the habitus of the patient. In searching for a tumor it is advisable not only to explore the entire anterior surface of the pancreas but also to mobilize the body and tail sufficiently from below to permit some rotation of it forward. This procedure will usually permit a partial examination of the posterior surface of the gland. The head of the pancreas may be examined by incising the lateral peritoneal reflection of the duodenum in such a way that it may be mobilized. On very rare occasions one will encounter a constant persistent hypoglycemia not associated with pancreatic tumor. In a case reported by Graham and Hartmann⁷ no tumor was found at operation on an infant one year of age who had well marked symptoms and who had shown blood sugar level indicative of hypoglycemia since the age of

three months. Accordingly in spite of the fact that the pancreas appeared normal subtotal resection of it was performed leaving only a small remnant of pancreatic tissue in the curve of the duodenum to protect the common bile duct. It was estimated that between 80 and 90 per cent of the pancreas was removed. Immediately after the operation the blood sugar value returned to normal and all of the symptoms of hypoglycemia disappeared. Previously the child's mentality had been markedly retarded probably because of the chronic hypoglycemia and this showed some definite improvement after operation. After ten years there has been no return of the hypoglycemic symptoms. This case is cited to call attention to the fact that if an attempt is made to remove pancreatic tissue where no tumor is present at least 80 or 90 per cent of the pancreas must be extirpated. However in most instances in which tumor is not present there is no primary overabundance of island tissue and the disorder can be taken care of by dietary measures even better than surgically. The use of certain chemicals that seem to possess the specific ability to destroy beta cells may be considered in certain instances. One must always bear in mind the frequency of moderate hypoglycemia in certain anxiety states.

It is probably a wise precaution to institute drainage in all cases after the removal of an adenoma or of any portion of the pancreas because in the majority of instances there will be an escape of pancreatic secretion for a variable period. In our experience such pancreatic drainage has never lasted longer than six weeks and is not associated with digestion of the surrounding tissues or of the skin that comes in contact with the secretions.

THE ADRENAL GLANDS

There are two adrenal or suprarenal glands found as the name implies in close association with the upper pole of the kidneys. Each gland consists of two parts, cortex and medulla which from the standpoint of their embryology and function are separate and distinct organs of internal secretion. The cortex is made up of columns of cells containing glistening granules of lipid material. It belongs to the so-called internal system and develops from the ventral part of the mesoderm which also gives rise to the sex glands. The medulla contains numerous nerve and ganglion cells and the characteristic large polygonal cells the chromaffin cells which take a brown color when stained with chromic acid. The medulla develops from that part of the ectoderm from which arises the sympathetic nervous system. Because of the intimate anatomical relationship between the adrenal cortex and medulla in man it is probable that both structures are often involved in the same disease process and a highly complex clinical disturbance is produced. While a great deal has been added to our knowledge of the function of these glands in the last few years much remains to be discovered. Aside from the treatment of primary tumors by extirpation or radiation surgery of the adrenal glands is at present in a frankly experimental stage and should be undertaken only by those who understand what they are about are conversant with the experimental literature in the field and are willing and able to make accurate observations of the effects produced.

THE ADRENAL CORTEX

Complete extirpation of both adrenal glands in most species results in death in a

few days following symptoms of anorexia, vascular collapse and depression. The cortex is the portion of the gland necessary for life since dogs have been maintained in good condition for long periods of time after removal of all trace of medullary tissue. It is now clear that this vital function of the cortex is performed by means of a specific internal secretion, active extracts of which have been obtained by Swingle and Pfaffner and Hartman. Careful subcutaneous or intravenous administration of this extract will preserve the life of an adrenalectomized animal indefinitely and correct all deficiency symptoms. The exact role played by the adrenal cortex or its hormone and the precise nature of the disturbance resulting from the loss of cortical function have not yet been determined. In some not well defined way it is concerned with circulatory efficiency, blood volume and the partition of water in the tissues, appetite and nutrition.

Hypofunction of the Adrenal Cortex—Sudden destruction of the adrenals occurs occasionally as a result of hemorrhage and is usually fatal in a few days. A gradual destruction of the glands produces the symptom complex known as *Addison's disease*. It is likely that this is a composite due to the loss of function of both cortex and medulla, the cortex playing the more important role. In from 80 to 90 per cent of cases the destruction of the gland is due to tubercle, the remainder being due to atrophy of an undetermined origin. The onset is usually insidious and the most prominent symptoms in the order of their occurrence are as follows: (1) fatigue, muscular weakness and general languor, (2) bronze pigmentation of the skin and mucous membranes, (3) anorexia, nausea and vomiting, (4) loss of weight, (5) arterial hypotension, (6) severe anemia and (7) circulatory collapse. The disease is progressive and although remissions occur surprisingly like the case of pernicious anemia, most patients eventually die. Treatment is symptomatic with the daily administration by subcutaneous or intravenous injection of an adequate amount of the aqueous extract containing the cortical hormone. The extract will control the clinical manifestations of Addison's disease in the majority of cases and its recent discovery has given new hope for this hitherto

measurable disease. The time is still too short to pass final judgment. At present however, the prognosis is extremely grave owing in part to the associated tuberculosis and to the difficulty and expense in securing adequate amounts of the potent extract.

Hyperfunction of the Adrenal Cortex
—Systemic symptoms due to long continued administration of excessive amounts of the cortical hormone have not yet been clearly defined. Our knowledge here is limited to the observations that have been recorded in cases of primary tumors of the adrenal cortex in which it is inferred that the tumor produces an excessive amount of hormone in a manner analogous to the situation in parathyroid adenoma and islet tumor of the pancreas. Primary tumors of the adrenals are unusually rare. Burke (1934) reports that of 46,000 hospital admissions a primary adrenal tumor was found in only 4 cases. Two of these were in the cortex and 2 in the medulla. These cortical tumors presumably through their elaboration of excessive amounts of the cortical hormone exert a profound effect on the development and function of the gonads. In the fetus such tumors have been found associated with pseudohermaphroditism; in the infant with excessive growth and early maturation of the external sex organs and secondary sex characters and in the adult female with virilism and hirsutism of the male type. Amenorrhea, hyperglycemia, obesity, acne, form eruptions of the skin and hypertension are more or less characteristic symptoms. A somewhat similar clinical picture has been observed in patients with basophilic adenomas of the anterior pituitary body and with certain types of ovarian tumors. Exploration of the adrenals is justified when other cause for the disease cannot be found or if there is local evidence of cortical tumor. In several instances the removal of a cortical adenoma or carcinoma has been followed by recovery or marked temporary improvement.

THE ADRENAL MEDULLA

In 1895 Oliver and Schafer discovered that intravenous injection of watery extracts of the adrenal glands would cause elevation of the blood pressure. Five years later Abel and Takamine isolated and synthesized adrenalin and in 1904 Elliott demonstrated

that the biologic effect of adrenalin was similar to that obtained by stimulating the sympathetic nerves. In 1905 Driver discovered that the stimulation of sympathetic fibers going to the adrenal glands would result in the liberation of increased amounts of adrenalin into the blood stream and raise the systemic blood pressure. By careful extraction experiments it has been demonstrated that most if not all of the adrenalin comes from the medulla and little or none from the cortex. On the basis of biologic tests it was believed by some of the early workers in this field that adrenalin exists in a constant but minute concentration in the circulating blood being supplied by a continuous secretion of the medulla. The assumption was made that this amount of adrenalin produces a continuous slight stimulation of the sympathetic system and thus through the vasomotor nerves maintains the blood pressure. The vascular collapse in Addison's disease and after adrenalectomy seemed to support this view. The demonstration however by Stewart and Rogoff and by Cannon that dogs can survive in good condition and with a normal blood pressure after removal of all trace of medullary tissue or after the removal of one adrenal and denervation of the other so that no adrenalin enters the blood stream proves that neither the adrenal medulla nor its product adrenalin is necessary for life or cardiovascular function. Cannon has supplied a convincing array of experimental evidence that whereas a continuous secretion of adrenalin does not occur under the stimulus of strong emotion evoked by conditions of stress there is an increased output from the glands. Since the physiologic effect of adrenalin is to increase the blood pressure, strengthen the heart beat, elevate the blood sugar value, increase the coagulability of the blood and shift the blood from the less insistent viscera to the organs immediately essential to life, Cannon believes that this response is purposeful and better enables the patient to meet the necessities of flight, combat or pursuit. In other words although adrenalin and the adrenal medulla may play little or no role in quiet comfortable existence they are very important in an emergency.

Hypofunction of the Adrenal Medulla
—It is probable that more or less complete

destruction of the adrenal medulla occurs in most cases of Addison's disease. The experimental evidence summarized above indicates that most of the symptoms of this disease are due to the associated destruction of the cortex and that a localized destruction of the medulla without involvement of the cortex would cause little or no disturbance. Such a patient might be expected to be less able to withstand the stress and strain of an unfavorable environment. It is of course well known that patients with Addison's disease are exceedingly poor surgical risks but in the present state of knowledge it is not possible to state whether this is due to the loss of the emergency function of the medulla or to the general effect of cortical insufficiency.

Hyperfunction of the Adrenal Medulla

—Systemic symptoms due to excessive excretion of epinephrine into the blood stream have been observed in a number of patients with a benign adenomatous tumor of the adrenal medulla. A tumor of this type is called a pheochromocytoma or pheochromocytoma and when it arises from the extramedullary chromaffin tissue a paraganglioma. Chromaffin cell tumor is probably the best name since the predominant cell type has the same origin and staining reactions as the chromaffin cells of the adrenal medulla. Patients with such a tumor have been found to display paroxysmal hypertension together with other symptoms such as pallor, profuse sweating, dyspnea, headache, precordial oppression, bradycardia, nausea and vomiting. The cause of the symptoms is a transitory and periodic outburst of epinephrine from the tumor which may sometimes be brought on by massage or the adoption of certain positions. Extirpation of the tumor with complete and permanent relief has been accomplished in a number of instances. The excised tumor has been found to contain large amounts of epinephrine. Removal of adrenal tumors may be accomplished through the usual kidney incision in those cases in which the tumor is large and its location is demonstrated by x-rays. Insufflation of air into the perirenal tissues is an aid in this delimitation. In most cases, however, it is best to make a transverse incision in the upper abdomen and explore both adrenals. The clinical picture of paroxysmal hyperten-

sion with its attendant phenomena is quite different from that of essential hypertension and there is little or no evidence that the latter is due to hyperfunction of the adrenal medulla. The reported association of hyperplasia of the adrenal medulla in these cases lacks confirmation. Prohaska, Harris and I were able to produce slight persistent hypertension in dogs by the continuous intravenous injection of epinephrine but the associated paralysis of the gastrointestinal tract and the disturbance in carbohydrate metabolism caused death within two weeks. The degree of hyperadrenalemia required to produce hypertension is thus sufficient to cause the death of the individual from the other systemic effects of the hormone. The suggestion that such diverse diseases as ulcer of the stomach and duodenum, hyperthyroidism, neurocirculatory asthenia and diabetes mellitus are due to hyperfunction of the adrenal medulla and may be corrected by adrenal denervation seems unlikely and there is little convincing evidence in its support.

In addition to the primary tumor described the adrenals are occasionally the site of metastases of a malignant epithelial tumor of the breast, esophagus, stomach, testicle or penis and of malignant melanoma. Such involvement is chiefly of pathologic interest.

XIII THE NERVOUS SYSTEM

HEAD INJURIES

It is the fractured skull which is exhibited in our museums not the damaged brain. But what has happened to the skull is of far less moment than what has happened to the brain and this has been given less study. (Cushing)

THE SCALP

The scalp is frequently traumatized. Surgically the galea aponeurotica a firm fibrous membrane joining the occipitofrontalis muscle and covering the calvarium is of primary importance. Overlying the galea and firmly bound to it by fibrous septa are subcutaneous tissue and skin beneath the galea and separated from it by loose irregular tissue like the pericranium. This membrane is closely adherent to the skull especially along the suture lines. The rich blood supply of the scalp is derived principally from the occipital, postauricular, temporal and supraorbital arteries which bleed freely when cut. The sensory nerves are the greater and lesser occipital, the auricular, temporal and supraorbital branches of the trigeminal. They have exceptional regenerative power and numbness of the scalp secondary to their severance ultimately disappears. When the motor branch of the facial nerve supplying the frontalis muscle is cut permanent ipsilateral paralysis of the forehead results a pertinent fact in planning surgical approaches.

Traumatic lesions include abrasions, contusions, hematomas, lacerations and avulsions that predispose to cellulitis, subaponeurotic or subperiosteal infections.

Abrasions or brush burns caused by friction may contain dirt. As the freshly abraded surface is moist with serum and exudate, vaselin gauze dressings give comfort. They are painlessly removed.

Contusions usually follow blunt blows on the resisting skull, the scalp occasionally becoming devitalized.

Hematomas may form beneath the galea or pericranium. A subaponeurotic hematoma

frequently assumes enormous proportions there being no limiting membrane to prevent its spread. The firm edges surrounding a central softened area may incorrectly suggest a depressed fracture especially if the galea or pericranium is ruptured. A roentgenogram clarifies the diagnosis. If in doubt one should explore rather than overlook a depressed fracture. Blood may spread for considerable distances under the scalp. A suffusion causing swelling and blackening of both eyelids is often associated with fractures in the frontal region. Following fracture or separation of the sagittal suture a hematoma may form in the midvertex from blood which seeps through the torn outer wall of the longitudinal sinus. This sometimes resembles a dunce cap. Hematomas usually absorb spontaneously. Aspiration or open evacuation is necessary only when the scalp becomes so tight as to impair its nutrition. Drainage is indicated in case of infection. Calcification of subperiosteal hematomas has been described.

Lacerations may be single or multiple, superficial or deep. Occasionally they bleed dangerously. If the aponeurotic or muscular fibers are cut transversely the wound retracts. Before lacerations are repaired the scalp should be liberally shaved, devitalized tissue debrided, all dirt removed and the condition of the underlying skull investigated to avoid overlooking a depressed fracture. Separate approximation of the galea with interrupted silk stitches strengthens the wound and permits early removal of the superficial sutures. Healing is prompt.

Avulsions—Glancing blows may lift large areas of the scalp, separation occurring in the subaponeurotic layer (scalping). Typical avulsions do not involve the bone. Conversely the calvarium is almost invariably injured in punctured or penetrating wounds. When avulsions are extensive, generous scalp flaps occasionally are required to secure closure. Ordinarily the prevention of scarring promotes healing, but if the pericranium is denuded the blood supply of the outer table

becomes impoverished requiring multiple perforations to the diploetic spaces. Granulation thus promoted may be skin grafted later.

Scalp infections when superficial occasion little disturbance. When they are deep beneath the galea suppuration may extend from the supraorbital to the occipital ridges whereas below the pericranium the attachments of this membrane limit the spread of pus. In either event suitable incisions favor relief preventing secondary osteomyelitis.

Diffuse cellulitis is of serious import. The infection may invade the pericranium and advancing by emissary and diploetic veins cause intracranial complications. Externally assuming erysipelatous characteristics it sometimes involves the entire scalp descending to the eyelids and face. Magnesium sulfate compresses (105° F.) are recommended. Fluctuating areas require adequate drainage. All scalp wounds should be dusted with sulfaamide powder before closure.

THE SKULL

The cranium consists of a dome-like vault rising above an irregular base. The former includes most of the frontal bone, both parietals, the squamous part of the temporal and occipital and the greater wings of the sphenoid. The base presents three fossae separated by bilaterally placed sphenoidal and petrosal ridges. The anterior fossa supports the frontal lobes of the cerebrum, the middle fossa its temporal lobes, the posterior fossa the cerebellum. The location of a basal fracture is suggested by the following signs: *Anterior cerebral fossa* (a) subconjunctival hemorrhage; (b) epistaxis if the arachnoid, dura and sclerodermal membranes are torn, and (c) anosmia from injury to the olfactory bulbs or filaments of the olfactory nerves as they cross the cribriform plate. *Middle cerebral fossa* (a) bleeding from one or both ears; (b) cerebrospinal otorrhea; (c) peripheral facial paralysis; (d) deafness or tinnitus; and (e) rarely tearing of the lateral sinuses or internal carotid artery. *Posterior or cerebellar fossa* (a) bleeding into the pharynx if the basilar process of the occipital bone is fractured and the pharyngeal mucosa torn, and (b) ecchymosis at the base of the neck and behind the mastoid (Peters).

Developed from membranous bone the calvarium presents inner and outer tables separated by spaces through which course the diploetic veins readily seen in roentgenograms. Not alone from its spherical shape but also from the stratified construction of its walls, layers of bone separated by potential space, the calvarium derives a maximum of strength, an important factor in resisting blows. Likewise the sutures modify the effect of external violence. The principal sutures never to be confused with fractures are the sagittal

coronal and lambdoid. At times however sutures are opened by injury, a result tantamount to fracture. Distinctive roentgenographic markings of the diploetic veins already mentioned must not be misinterpreted for fracture. Similarly the middle meningeal arteries often deeply groove the temporal and parietal bones, but the direction and branching are characteristic. If one of these vessels is torn by a fracture extracranial hemorrhage may result. Fractures of the vault heal not by callus but by membranous union. Owing to the slight regenerative power of the bone traumatic or operative defects seldom close. To the pericranium and dura some writers ascribe weak osteogenic functions.

Cartilaginous in origin the base of the skull is much thinner than the vault, separation into tables does not obtain and the floor is penetrated by foramina for the passage of nerves and vessels. The thinnest and weakest part of the floor, that of the middle fossa, is the favorite site of basal fractures. The dura adhering more closely to the base than to the vault is most frequently torn in basal fractures. A ring of dense bone about the various foramina protects the structures which traverse them.

Skull Fractures—Here elaborate classifications have little practical value. Fractures have been grouped according to location and type. They may be *linear* (fissured, bursting, expansile), *depressed* (indented, stellate) or *penetrating*.

Linear fractures are most frequent. Their production depends on certain elastic qualities of the skull. If sufficient force is brought against it the skull will be shortened in one diameter, lengthened in another and fracture results from increasing its equatorial circumference. The mechanism resembles that of cracking a nut. Almost invariably the line of fracture follows the direction of the shortest meridian. Naturally linear fractures have various locations and peculiarities because the offending forces differ in intensity and direction and because the cranium is not a perfect sphere. At first the fracture line separates but immediately springs together. If the scalp is simultaneously lacerated and hair or other foreign matter is entrapped in the fracture line the likelihood of infection increases.

Since the base of the skull is its weakest part it is the most common site of fracture. When the line crosses the middle fossa and the dura and eardrum have been ruptured bleeding occurs from one or both ears. Obviously such a fracture is compounded and carries increasing danger of meningitis. Occasionally when the ear does not bleed ex-

ternally inspection discloses a drum bluish and bulging from hemorrhage into the middle ear indisputable evidence of a basal fracture. These can seldom be demonstrated roentgenologically the bleeding ear furnishes the clue. The same significance attaches to blackening of both eyes or cerebrospinal rhinorrhea. Although linear fractures generally avoid the buttresses of the skull they may cross the supraorbital ridges invade the mastoid or enter the foramen magnum. If they communicate with the large basal cisternae the danger of meningitis is increased. Linear fractures heal slowly and demand no treatment.

Depressed fractures although less frequent than linear are more important from the standpoint of surgical treatment. Caused by

compression the mosaic pattern can be reconstructed before the fragments are replaced. Fragments are often viable even in the presence of infection. Later should signs of osteomyelitis appear their removal is simple. Indriven fragments which lacerate the dura should be carefully removed. They are a source of cerebral irritation. The dura should be repaired if possible drainage is seldom necessary.

Indentations from obstetrical forceps or pressure of other kinds incidental to birth should be elevated. The question often arises regarding the advisability of elevating small depressed fractures which give no objective neurologic signs. While their elevation may not always be necessary it is better to advise it. Only by correction of the depressed

Fig. 118—A comminuted depressed skull fracture viewed from outer and inner aspects. The inner table is all ways more extensively fractured. In correcting such a fracture all fragments should be accounted for and if possible replaced. (Cushig)

direct force like a hammer blow they are often compound and possess an almost constant peculiarity. If both tables are involved as is usually the case the inner table is more extensively fractured than the outer. This is explained on the principle that the outer table is crowded together by external force while the inner table is spread until its tensile strength is overcome. Therein it resembles a greenstick fracture of a long bone where the part opposite the point of applied force suffers most because it is under the greatest strain (Fig. 118).

When elevating a fracture of this type it is imperative to include the depressed inner table. Much too frequently the outer table is corrected the inner untouched. All fragments should be saved to fill the defect since skull bones have little power of regen-

eration. The mosaic pattern can be reconstructed before the fragments are replaced. The possibility of subsequent convulsions be minimized to the greatest extent.

Penetrating fractures invariably compound result from high velocity projectiles or sharp objects which strike the skull with great force. The torn dura permits bone fragments to be driven into the brain. Penetrating fractures are essentially depressed with the additional features which arise from entrance into the brain of foreign substances, i.e. the missile bone fragments hair or dirt. *Post-traumatic convulsions are frequent.*

Unless contraindicated by the patient's condition penetrating fractures demand surgical attention. Preliminarily the entire scalp is shaved and the wound carefully cleansed. Occasionally the wound must be enlarged and the fragments removed en bloc with

some surrounding bone. The macerated brain pouts through the torn dura. With a catheter the missile tract is gently irrigated

Fig 119—Diagram illustrating the methods of treating penetrating fractures. The tract is irrigated with a catheter, bone fragments and disorganized brain tissue being washed out. The missile often can be seen and easily removed with forceps (Cushing)

with sterile normal salt solution (Fig. 119), and detritus and bone fragments are sucked out. Every bone fragment should be re-

Fig 120—Roentgenogram illustrating several conditions in gunshot wounds of the skull. Indriven metal and bone fragments surround the portal of entry. The bullet has ricocheted from the top of the skull and lodged posteriorly. A typical bursting fracture is produced.

moved, otherwise it may become a nidus for subsequent brain abscess. Particles of metal should be removed when accessible. It is poor judgment to lacerate the brain for this

purpose unnecessarily. "When a bullet has stopped it has done its damage," though axiomatic, is sound teaching. A high velocity missile creates considerable disorganization of the brain substance along its track, caused by the expansile force of the projectile (Fig. 120). Such wounds should be explored early, dusted with sulfanilamide powder and drained or closed tightly.

Traumatic osteomyelitis sometimes follows bruising of the scalp though the bone remains intact. More often it results from infection of a compound, depressed fracture. Usually the process affects both tables of the

Fig 121—Osteomyelitis secondary to compound, comminuted depressed fracture of the frontal bone. The rarefying osteomyelitic fragments required removal. A concomitant frontal lobe abscess was drained.

skull, either slowly or rapidly. If slowly, it assumes a sclerosing form and remains localized. The gathering of pus under an infected scalp and outside the dura gives a tender, fluctuant swelling, long known as "Pott's puffy tumor." If spontaneous rupture fails, incision is necessary; subsequently fragments of dead bone are intermittently discharged for many months. Sequestered fragments are easily removed under local anesthesia. With the disappearance of all diseased bone, the wound heals promptly.

The fulminating type of osteomyelitis spreads in the diploetic spaces and traveling to distant parts of the skull establishes fresh

foci Thrombosis of the diploetic veins checks its advance. With this type the diseased bone becomes rarefied and porous in contradistinction to the increased density produced by the sclerosing variety. Roentgenographically one can readily differentiate between them. Efficient drainage should be established and sequestration awaited even though fragments are discharged for a long time. To attempt wide excision of acute osteomyelitic areas is poor judgment. Such attempts are rarely successful as fresh channels are opened through which the infection extends. Epidural or subdural abscesses are familiar complications and cerebral abscesses meningitis and sinus thrombosis not infrequent (Fig 121).

Hematomas of the scalp may become infected the process spreading to the underlying bone, particularly if the pericranium has been ruptured. Occasionally, osteomyelitis of the skull follows diffuse cellulitis of the scalp. It may be blood borne. In syphilitic patients an osteomyelitis most often in the frontal region, may follow a slight scalp bruise. Antiseptic treatment ordinarily suffices.

THE BRAIN

Anatomical and Physiologic Considerations.—The brain has two protective coverings the *pachymeninx* or *dura mater* and the *leptomeninx*. The former a tough fibrous relatively non-elastic membrane adheres closely to the inner table of the skull. It assumes the role of an endosteum. Together with the pericranium it furnishes the blood supply to the calvarium the major contribution being made by the dura. This membrane consists of two closely adherent layers which separate at appropriate points to permit the passage of large venous channels and nerve structures.

The intracranial cavity is roughly divided into three chambers by the *fals cerebri* and *tentorium cerebelli*. To furnish passage for the longitudinal sinus the two layers of the *fals* separate. It extends anteroposteriorly from the crista galli to the internal occipital protuberance where it joins the tentorium cerebelli the union of these membranes enclosing the straight sinus. Its lower margin hugs the corpus callosum which separates and protects the cerebral hemispheres. The *tentorium cerebelli* separates the cerebellum from the occipital lobes partitioning the intracranial cavity into the so-called supratentorial and subtentorial chambers. The *fals* and tentorium protect the brain against injury.

The *leptomeninx* includes the *pia arachnoid*. The *pia*, a very delicate membrane closely covers the cerebral convolutions. The *arachnoid* is a loose spider's web-like meshwork in which circulates the cerebrospinal fluid. Between the *pachymeninx* and the *leptomeninx*

exists a potential area called the subdural space. Its importance relates to subdural lesions hemorrhage chronic hematoma and hydroema.

A water bed surrounds the brain. The cerebrospinal fluid is chiefly elaborated by the choroid plexuses situated in the two lateral and the third and fourth ventricles respectively. The fluid formed in the lateral ventricles passes through the foramina of Monro into the third ventricle and with further additions is conducted by the aqueduct of Sylvius to the fourth ventricle. After further slight addition of fluid it passes through the foramen of Magendie and the foramina of Luschka into the subarachnoid spaces. The passage of cerebrospinal fluid from the ventricles through the various subarachnoid spaces is sometimes called "the fluid circulation." It flows forward along the base of the brain to reach the subarachnoid spaces over the cerebral hemispheres where it is largely absorbed. Its method of absorption like that of formation is not clearly understood. It is chiefly absorbed by the pachionian granulations which empty through venous radicals into the longitudinal sinus. Other methods of absorption include osmosis through widely distributed capillary walls and arachnoid structures. While passing along the base of the brain the fluid traverses structures resembling lakes or cisternae. Important among these are the cisterna magna the cisterna in terpeduncularis and the cisterna chiasmatica. They afford added protection to the delicate neural structures composing the base of the brain. However they become potential points of danger whenever a compound basal fracture communicates with them for in section so introduced almost invariably leads to meningitis. The water bed thus not beneath the temporal and frontal lobes. This fact combined with the frequency of blows on the occiput or vault suggests why the tips and under surfaces of these lobes more often show bruising than do other parts of the brain. Contusion at a point opposite where a blow is struck is designated "contre-coup" hemorrhage there is called hemorrhage by "contre-coup."

Following injury blood may enter the cerebrospinal fluid pathways including the ventricles the aqueduct of Sylvius and the subarachnoid spaces. When these rupture fluid collects in the subdural space. It is absorbed mostly in the subarachnoid spaces but occasionally blocks the aqueduct first causing ventricle formation and later internal hydrocephalus.

Increased Intracranial Pressure: Physiologic Considerations.—In considering brain injuries certain physiologic facts become fundamental. The cranium a relatively closed cavity with unyielding walls is filled completely with the brain and various free fluids including arterial and venous blood and the circulating cerebrospinal fluid. One must also include interstitial fluid bound by cell plasma. All these are incompressible. The importance of these fluids becomes evident when after injury, the brain swells. The situation then resembles that produced

by a tight cast enclosing a broken leg. As swelling proceeds, accommodation for the brain is favored by the outflow of cerebrospinal fluid and venous blood. If edema is not marked sufficient room may thus be provided. Greater swelling which raises the intracranial above the venous pressure collapses the cerebral veins. Congestion of the brain follows for arterial blood still can enter but the escape of venous blood and cerebrospinal fluid is impaired. Extreme swelling which raises the intracranial pressure above the arterial effectively blocks the further inlet of blood. Anemia of the medullary centers follows and death results.

The centers in the brain stem controlling respiration, pulse rate and pulse pressure are readily affected by alterations in intracranial

Cheyne Stokes respiration associated with a sudden rise in pulse rate and a concomitant fall in blood pressure is an ominous sign indicating failure of these vital centers.

The heat regulating center situated near the floor of the third ventricle likewise may be affected. When the intracranial pressure is high there are fluctuations in temperature varying from less than one degree to eight or more degrees. A daily variation of two or more degrees is considered characteristic of cerebral contusion. As intracranial tension drops the temperature falls intermittently to normal the regression may take days or weeks (Fig. 122). However if intracranial pressure becomes excessive control of the heat regulating center is lost and hyperthermia results. When this occurs strange it

Fig. 122—Characteristic clinical course in cerebral contusion showing diminishing intermittent temperature with corresponding alterations in pulse and respiration rates.

pressure. Whenever the blood pressure alternately rises above and falls below the intracranial tension characteristic fluctuations occur in breathing (Cheyne Stokes respiration) always a danger sign. Moreover as the vasomotor center is stimulated the pulse pressure rises for the arterial pressure must remain above the intracranial pressure to have life continue. The vasomotor and cardioinhibitory centers function in response to variations between the intracranial and the arterial pressure.

As death approaches the respiratory center fails first and breathing ceases then the vasomotor center collapses causing a sudden drop of blood pressure finally the cardioinhibitory center gives way with a rising pulse and cardiac failure. Breathing stops several minutes before the heart beats

say the patient seldom sweats. A terminal fever often reaches 106° F. or more.

Gross Pathologic Changes—The gravity of a head injury depends on the degree of damage to the brain. While it is important to know whether or not the skull has been fractured it is far more essential to ascertain how severely the brain has been injured. Trauma most commonly causes cerebral edema. Grossly little is found. That the brain's fluid content is increased is shown at operation by sweating of the arachnoid and at postmortem examination by unusual wetness. Much of the fluid is held in the cytoplasm and perivascular spaces. The choroid plexuses appear reddened and swollen and the amount of circulating cerebrospinal fluid is increased. Pronounced cerebral edema flattens the cerebral convolutions and congests

the vessels. Petechial hemorrhages when present indicate more than simple edema.

Fig. 123—Basal view of extensive petechial contusion. The frontal lobes have sustained the brunt of the force but the cerebellum and the petechiae also show damage. The olfactory bulbs have been crushed (frequently a cause of anosmia). Subarachnoid hemorrhage is seen in the cisterns.

Contusion of the brain likely to occur anywhere is most frequent along its base.

head in rapid motion is suddenly stopped the brain being bruised by impact against the unyielding skull. When the head at rest is struck contusion occurs beneath the point of impact or by contre coup. Contusions often multiple minute or extensive are accompanied by rupture of adjacent vessels (Fig. 123).

Subarachnoid hemorrhage associated with cerebral contusions varies in degree when extensive it covers most of the hemisphere. Its red appearance in life contrasts with the dark currant jelly color at autopsy. Usually the arachnoid membrane is torn permitting seepage into the subdural spaces thus confusing the diagnosis (Fig. 124).

Petechial hemorrhages having grossly a fine spider bite appearance are formed by capillary rupture with extravasation of blood into the perivascular spaces. More numerous in the white than the gray matter they tend to collect toward the base of the brain and in its stem. Ultimately they show patchy gliosis.

Subcortical hemorrhages varying in size are frequently associated with lacerations of the cortex. If near the motor area they predispose to contralateral hemiplegia which appears suddenly in contradistinction to its gradual development following epidural hemorrhages (Fig. 125).

Lacerations of the brain frequently accom-

Fig. 124—Widespread subarachnoid hemorrhage a frequent finding which is often associated with secondary flooding of the subdural space.

The predominant locations are at the tip and under surfaces of the temporal and frontal lobes. Contusion follows when the

parietal depressed or penetrating fractures vary in extent and depth proportionate with the force producing them. In driven bone

fragments or foreign bodies may be deeply embedded. Lacerations produced by through and through gunshot wounds traverse the

into the interstitial tissues, may be present (Fig 126). The ependymal cells become swollen with lakes of fluid within their protoplasm (Fig 126, b). At times fluid expands the perivascular spaces (Virchow-Robin). Whether true pericellular spaces normally exist is not settled but following injury fluid frequently surrounds the ganglion cells. The oligodendroglia cells show widespread acute swelling (Fig 126 c). Soon after injury the microglia cells show transitional changes and assume the role of phagocytes engulfing degenerated brain tissue erythrocytes myelin and other debris. Fully developed they are called compound granular corpuscles. Their activity is purely local, that of the oligodendroglia general. Contusion destroys the ganglion cells with interruption of their fibers which in the process of degeneration develop peculiar end bulb formations. Gliosis is first shown by changes in the neuroglia cells with abundant increase of astrocytes. Patchy, or widely distributed gliosis occurs only where actual brain damage has taken place. Many of these finer changes in the interstitial tissues are demonstrable only by Cajal's reduced silver staining methods (Fig 127). The microscope also reveals the proliferation of new blood vessels with fibroblastic elements and connective tissue, the collection of red corpuscles in the subarachnoid spaces especially the

Fig 125—Massive subcortical and ventricular hemorrhage shown in tangential section

entire brain. Rarely cerebral laceration occurs without skull fracture.

Microscopic Pathologic Changes—Microscopic changes are so numerous that they

Fig 126—*a* Extensive edema of choroid plexus four hours after injury; hematoxylin and eosin $\times 190$. *b* marked swelling and distortion of epithelium with edema of subependymal tissue two days after injury; hematoxylin and eosin $\times 170$. *c* widespread acute swelling of oligodendroglia. The ring like outline of the cells' nuclei is plainly shown. Penfield's combined method $\times 700$ (Rand and Courville).

may only be enumerated. In cerebral edema, the living cells of the choroid plexuses swell and vacuolization is increased. Edema and hyperemia of the vessels even hemorrhage

sulci, fine adhesions between the pia and the cortex, ischaemic changes and chromatolysis of the ganglion cells, blood pigment inclusion in ganglion cells, and multiple petechial

hemorrhages. These histologic changes serve to explain certain symptoms mentioned later under postconcussional syndrome.

Symptoms—The symptoms resulting from craniocerebral injuries customarily are discussed under the headings *concussion*, *contusion*, and *compression*. With the terms one should be familiar but it is important to realize that the entities they define merge into each other being seldom clinically distinct. Reaction of the brain often reaches its peak within two hours after in-

jury. A contestant, knocked out ten seconds to resume fighting. A patient rendered unconscious has no recollection of the blow. The last he remembers is some incident shortly before the injury. The next is awakening with a headache. For an instant following the blow physiologic processes practically stop; the pulse is imperceptible, breathing ceases, there is no response to sensory stimuli, the pupils dilate and the body is limp. However, reaction soon takes place on recovery of consciousness the patient usually

FIG. 197.—Diagrammatic illustration of neuroglial reaction in late stage. Actively proliferating astrocytes have been plagiocytosed and removed. The arrows indicate the location of cellular migration. I shows the zone of immediate destruction. II the zone of secondary or delayed destruction. III the zone of reversible reaction. IV the zone of reactive gliosis. a. Compacted glial corpuscles arising from the mesodermal elements of the regional blood vessels (in white substance). b. proliferation of fibrillasts to form fibrillar reactive tissue scar. c. fibrillogenesis. d. hyperchromatic nuclei (of neuroglial nature). e. dendrocytogenesis of slowly disintegrating astrocyte. f. patches of chronically altered neuropil. g. bipolar, tripolar, multipolar and multipolar forms undergoing reversal reaction. h. fused red multipolar astrocytes (giant cells) showing regressive changes. a. b. hypertrophy and proliferation of fibrous astrocytes (Coryell).

jury. Hence a complexity of symptoms may develop with amazing rapidity.

Concussion difficult of description generally implies unconsciousness profound or momentary resulting from a blow on the head. Perhaps it is best defined as a series of events resulting from a blow to the head severe enough to cause disruption of intracranial equilibrium (Strauss and Savitsky). Here plainly is the implication of commotion cerebri. The brevity of the period of unconsciousness in simple concussion is attested by the rules of the prize ring which

allows a contestant, knocked out ten seconds to resume fighting. With the resumption of activity dizziness appears. Vomiting instability may persist for weeks.

What happens during concussion? Momentary interruption of the function of the nerve cell. Beyond this the explanation is theoretical. The suggestions which have been made include paring of the neurons, separation of the synapses, temporary increase in coagulation of the cell plasma and a sudden increase of electrical discharge. Some hold vasomotor changes responsible. Only rarely does simple concussion cause death and

then gross pathologic lesions are difficult to find

Contusion and compression are difficult of clinical differentiation. This is not strange when one reflects that contusion implies edema, bruising and bleeding and one of which may cause increased intracranial pressure. Unsuspected but sizable lacerations of the brain are often present. The initial clinical symptoms of contusion are essentially those of concussion. However instead of recovering promptly as with concussion the patient remains comatose for hours, days or weeks. Periods of restlessness to a point of violence particularly in alcoholic persons may intervene. The duration of unconsciousness as recorded clinically and as ultimately estimated by the patient differs widely. Always the patient's estimate is longer. Many automatic acts such as eating, talking or driving a car are not later recalled. The prevailing degree of consciousness is the best single index of the patient's condition. As intracranial pressure increases coma deepens as it lessens the patient's mind becomes clearer.

Contusion causes vomiting sudden explosive projectile which is increased by movement of the head. The vomitus often contains swallowed blood.

Daily fluctuation of temperature is characteristic of contusion. The pulse rate varies from moderate slowing in mild contusion to marked slowing in severe pressure. A pulse rate below 60 signifies danger. Concomitant increase in blood pressure accompanies this bradycardia giving a hard slow pulse. A sudden increase in the pulse rate associated with falling blood pressure indicates failure of the medullary centers. Respiration ordinarily becomes slow and deep in contusion and labored or Cheyne Stokes in compression.

Headache appears as stupor lightens throbbing at first it continues with decreasing severity for weeks or months. Since exertion increases the pain a recumbent position is essential. The patient who remains in bed for the first few weeks materially shortens his convalescence.

Posture—A patient with cerebral contusion usually assumes a striking attitude. Characteristically he lies curled on his side in a position that is almost pathognomonic.

Urinary incontinence often heralds incoming coma. Leukocytosis with from 10 000 to 20 000 cells is a transient phenomenon.

Cranial Nerve Complications—The cranial nerves may be temporarily or permanently damaged following head injuries. Frequently single nerves and occasionally groups are affected as they traverse their foramina of exit.

I Olfactory—Anosmia is most often associated with fractures which transverse the anterior fossa in the region of the cribriform plate. It results frequently from contusion or laceration of the under surfaces of the frontal lobes in which the olfactory bulbs or nerves participate. Their filaments may be torn in passing through the cribriform plate. Anosmia is almost invariably permanent as nerves of special sense lack the power of regeneration (Fig 123). Usually bilateral and complete it is sometimes unilateral and incomplete. It is doubly annoying since not only is the sense of smell lost but that of taste is secondarily affected. In certain occupations it constitutes a real disability.

II Optic—The eyegrounds should be repeatedly examined. Choked disk appears relatively late the fundi showing no elevation for the first few days after injury. Conversely retinal hyperemia occurs early. By watching the increasing engorgement one obtains a fair estimate of the advancing intracranial pressure. Choking is the rule in chronic subdural hematoma and hydroma. It occurs with brain abscess following a penetrating fracture and to a high degree if the aqueduct of Sylvius is blocked by an organized clot. Occasionally choked disk follows craniocerebral injuries unaccompanied by headache, nausea, vomiting or objective neurological signs. Usually it subsides spontaneously and its explanation remains speculative.

If the optic nerves are injured directly blindness is immediate and permanent. Unilateral blindness due to injury of the corresponding optic nerve near the optic foramen infrequently occurs. Bilateral blindness due to severance of both optic nerves occasionally follows self-inflicted gunshot wounds. Traumatism of the nerve causes primary optic atrophy. The disk of pearl whiteness presents sharp margins, the optic cups and

lamina cribrosa are distinct the arteries are often thread like

Bitemporal hemianopsia secondary to splitting of the optic chiasm in an antero posterior direction, is rare. When present it remains permanent. Concomitant injury of the infundibulum occasionally causes diabetes insipidus (Fig 128)

Hemianopsias directly caused by injury of the optic radiation in gun hot wounds and indirectly in cases of chronic subdural hematoma have been described

III Oculomotor II Trochlear VI Abducens—Injury to these nerves causes diplopia. With involvement of all three nerves ophthalmoplegia results. The oculomotor or

The trochlear nerve is rarely involved alone. When it is there is difficulty in looking downward and outward on the affected side, the patient sees double when going downstairs

I Trigeminal—If the infraorbital branches of the trigeminal nerve have been torn by fracture of the maxillary bone anesthesia or paresthesia along the nose and upper lip develops. The upper teeth are affected when the dental branches are caught. In spite of the tendency of the trigeminal nerve to regenerate complete recovery of an injured infraorbital branch seldom occurs. Consequently subjective discomforts secondary to paresthesia of the face persist. Rarely the

Fig. 129—Bitemporal hemianopsia following injury to the optic chiasm. Temporary diabetes insipidus was an accompanying symptom.

the trochlear or both nerves are apt to be associated with injury of the abducens

The *abducens* the longest cranial nerve is frequently affected. The lesion occurs anywhere from the nucleus of its origin to its passage through the sphenoidal fissure. It is often affected in basal fractures associated with hemorrhage. With complete paralysis there is internal strabismus and inability to turn the eyeball outward. Slow recovery is the rule

Complete *oculomotor* paralysis results in external strabismus, ptosis and dilatation of the pupil. The dilatation always of great importance signifies an ipsilateral intracranial lesion. The dilated pupil reacts to light more sluggishly than its mate. Accommodation suffers less. Anisocoria persists indefinitely and may become permanent

gasserian ganglion injured and very rarely its sensory root torn. My own experience include an instance of anesthesia in the entire trigeminal supply which continued years after injury. Presumably this signified severance of the sensory root, the motor root escaping

II Facial—This nerve is rarely torn at its exit from the pons more frequently in its passage through the temporal bone. Most frequently facial paralysis complete or incomplete is accompanied by bleeding from the ear. Bleeding into the facial canal or edema of the nerve may cause pressure on this structure resulting in a peripheral facial paralysis. Unable to modulate the features on the affected side the patient cannot wrinkle his forehead or close his eye. Paralysis of central origin must be distinguished

from the peripheral type. In the central type closure of the eye on the affected side and equal wrinkling of the forehead are unhampered. The paralysis may be permanent. However recovery preceded by fibrillation or twitching may begin shortly strength returning first in the forehead or at the angle of the mouth. One portion of the nerve may recover more completely than another.

Toward securing the desired result massage of the face should be begun early and applied to both the inside and the outside of the cheek. Rotary movements directed upward are most effective. This treatment the patient carries out for himself accurately timed ten minutes three times a day. He should also attempt voluntary movement of the face before a looking glass. The eye should be protected. Electrotherapy has its place. Adhesive straps applied to the face give support.

VIII Auditory—This nerve consists of two portions, the cochlear concerned with hearing the vestibular with equilibration. It is the most frequently affected cranial nerve. It is vulnerable as it passes from the pons to the internal auditory canal and may be torn across or avulsed in this region. The predominant injuries however occur as it traverses the temporal bone.

Cochlear portion Disturbances of hearing are common especially in basal fractures associated with bleeding from the ear. Diminution of hearing with islands of deafness revealed by the audiometer is the rule. One or both ears may be affected. While ultimate improvement ordinarily occurs complete restoration of hearing seldom takes place. Tinnitus whether unilateral or bilateral may be high pitched and faint or low and of greater intensity, a most annoying and persistent symptom sufficient at times to keep a patient bedridden.

Vestibular portion Disturbances of equilibration prominent after effects of head injuries become more noticeable with resumption of activity. Apparently they are due to disturbance of both the peripheral and the central vestibular apparatus. One or both nerves may be affected seldom equally. The vertigo or dizziness is accentuated by sudden changes in the position of the head. It is often described as giddiness or light-headedness and is usually of short duration.

Merely looking up brings it on. However it constitutes a disabling symptom in the trades which require climbing. In the majority of cases neuro-otologic studies reveal abnormal vestibular responses. The tests are not least valuable because they serve to identify malingerers.

IX Glossopharyngeal V Vagus X Spinal Accessory XI Hypoglossal—These well protected nerves are seldom damaged. The glossopharyngeal, vagus and spinal accessory may be directly injured by a missile penetrating the jugular foramen. The writer has never seen an injury to the hypoglossal nerve.

Examination of the Patient—Since signs and symptoms change rapidly repeated examinations are imperative. Internal injuries or fractures of long bones may be revealed. A complete neurological survey soon after injury is seldom possible as the patient cannot cooperate. The degree of consciousness should be noted and followed as it is one of the best indices of the gravity of the case. Whenever possible the cranial nerves should be examined serially. The eye grounds should be examined daily even though early choking of the disks is not to be expected and special attention paid to the equality of the pupils and their reaction to light. A dilated pupil must be regarded with suspicion it may be the straw pointing to the side of the lesion. Oculomotor palsies and diplopia should be noted. Inspection of the ear drum seldom necessary may do harm if the ear is bleeding. Weakness of the face will be recorded as central or peripheral. Disturbances of speech require analysis. In right-handed persons a slowly developing aphasia usually indicates a progressive lesion of the left temporal or frontal lobe. Jargon aphasia should not be confused with irrationality. The visual fields should be examined grossly. Careful observation in a semiconscious patient will often disclose a hemiplegia or hemiparesis. Stimulation of the member will emphasize this. One should watch for signs of convulsions and hemiplegia. The type of convulsions focal or general should be carefully noted. Incoordination in the use of an extremity is important. The reflexes must be surveyed carefully and repeatedly for inequality or change. An ankle clonus, positive Babinski, Oppenheim or Gordon sign is sig-

nificant Immediately after severe head injuries all reflexes superficial and deep are lost Their return signifies a favorable reaction their failure to do so is ominous Pulse rate, temperature and respiration should be recorded frequently and the blood pressure carefully followed

The Spinal Fluid—Following head injuries the volume of spinal fluid increases Not only is its rate of production augmented but its absorption is disturbed Opinions differ with regard to the advisability of lumbar puncture Some believe that the procedure is dangerous and should never be employed others advocate its routine use A middle course would seem more rational Laboratory study of the spinal fluid yields valuable information The measurement of its pressure furnishes a close estimate of the prevailing intracranial tension A water manometer is preferable (Fig 129) Lumbar puncture should be done with the patient lying on his side in position in which the pressure ranges normally from 100 to 150 mm of water (8 to 12 mm of mercury) In severe injuries it often exceeds 400 mm Its reduction should be carried out slowly, allowing the fluid to escape drop by drop The patient's pulse and respiration must be carefully watched as material change of either means the needle should be withdrawn Daily manometer readings will usually show a gradual drop of spinal fluid pressure Lumbar puncture is condemned if there are signs of medullary disturbance Although respiratory embarrassment and hyperthermia are occasionally relieved by spinal puncture in desperate cases it is likely to do more harm than good The procedure is ill advised whenever the patient is not easily controlled

The amount of free blood in the fluid indicates the degree of intracranial bleeding Obviously the blood removed by puncture is but a small per cent of that actually present Experiments have taught that the subarachnoid spaces absorb blood rapidly Daily examinations show an amazing decrease in the relative amount of blood the fluid first becoming xanthochromic then colorless Repeated punctures and the use of sulfa drugs or of penicillin are recommended in cases of meningitis They seldom save life but they do relieve headache Strictest asepsis is necessary

Roentgenologic Studies—*Stereoscopic examination* of the skull is essential A favorable moment should be chosen as satisfactory plates of a restless patient cannot be taken Shock is a contraindication In depressed or penetrating fractures one can visualize the extent of the depression or the location of driven bone fragments or foreign bodies As linear fractures in themselves require no treatment their identification has

Fig 129—Simple Lomax-type manometer for spinal fluid study A 20-gauge chromium needle is used The manometer consists of an ordinary 1 mm bore glass tube cut to 200 mm length The spring on the bulb represents 50 mm A glass sphygmomanometer joined to the first manometer by rubber tubing is readily attached to the needle after puncture Should the pressure measure more than 400 mm a second manometer is united to the first The apparatus is easily made and very a light article

little clinical importance unless they communicate with the paranasal sinuses or cross a grooving vessel Many cases showing extensive linear fractures have relatively little cerebral damage and vice versa The two conditions must be kept distinct

Encephalography never to be employed in acute cases gives valuable information regarding late sequelae The puncture is made preferably with the patient lying on his side Fractional removal of the fluid is

secured by gradually raising the head of the operating table. In order to obtain good roentgenograms from 90 to 140 cc of fluid must be removed and replaced with a slightly smaller amount of air. The difference permits expansion of the air caused by the body's higher temperature thus avoiding the danger of increasing the intracranial pressure. If the pressure is already high encephalography is contraindicated. In a case presenting a postconcussional syndrome encephalography reveals more or less cortical atrophy and enlargement of the ventricles. Occasionally the post traumatic headache is thus relieved.

Fig. 130—Ventriculogram showing both ventricles pushed to the left by a chronic subdural hematoma occupying the right frontal region.

Ventriculography—the method of choice in cases of high intracranial pressure gives valuable information in cases of chronic subdural hematomas, latent abscess and hydrocephalus secondary to blocking of the aqueduct or the eisterna magna (Fig. 130).

Treatment—*Constant watchfulness is essential.* Routine treatment cannot be outlined as no two cases are alike and unexpected complications often occur. Many patients are badly shocked and for the moment shock is of more concern than the craniocerebral injury. Rapid and careless transportation is condemned. Body heat should be maintained and stimulation administered as needed. Bleeding from external wounds should be staunched. The

administration of fluids in sufficient amounts orally or by hypodermoclysis or even blood transfusion may be necessary. The period of shock sometimes prolonged usually passes within a few hours.

By far the most valuable single measure in the treatment of head injuries is *rest in bed which should continue until all indications of increased intracranial pressure have subsided.* At times this is difficult. Opinionated patients should be told that rest is their best insurance against post-traumatic headache and dizziness. The patient should remain quiet until all headache has disappeared and then is allowed up slowly. If headache returns he should again go to bed. Even after a simple concussion several days of rest is desirable. After more severe injuries from four weeks to several months may be necessary. Rest should be maintained until cerebral vasomotor stability becomes reestablished. It is an impressive fact that patients with head injuries who are forced to rest for long periods because of other fractures simultaneously incurred convalesce most satisfactorily.

Ice to the head with merits long ago recognized proves most effective when several bags are used together. A single bag has little value. Patients welcome cold which benumbs the scalp and lessens pain. The exceptional patient who resists treatment should be humored. Elevating the head of the bed reduces cerebral congestion.

The use of sedatives requires sound judgment. Depressing drugs should be avoided. Morphine employed too generally masks symptoms; it produces sleep indistinguishable from coma; it depresses further an already embarrassed respiratory center and its narcotic effect nullifies the localizing value of a dilated pupil. Occasionally morphine is helpful but it should always be used sparingly. The effect of each small dose should be ascertained before another is given. A nurse's judgment should not be relied on in this regard. Generally codeine is preferable to morphine though the latter may be indicated for shock or pain from internal injuries. Chloral sodium, amytal, sodium luminal and paraldehyde are safer than morphine. Caffeine sodium benzoate an excellent stimulant is said to lower the intracranial pressure and combat shock.

The pulse rate respiration temperature and blood pressure should be charted at intervals of an hour or less during acute phases Icebags to combat hyperthermia placed over the carotid axillary femoral and popliteal arteries may be removed after the temperature falls below 102°F For the same purpose ice water enemas alcohol and tepid sponges are employed

Reported turning in bed does not require restraint A patient often prefers to lie on his side and restraining him on his back only increases the restlessness Securing the wrists and ankles with loosely tied sheets ordinarily provides adequate restraint especially when supplemented with well padded side boards A restraining jacket is seldom necessary

A bleeding ear should be left alone or at most loosely packed with dry sterile cotton The bleeding usually stops within a few hours or days Nature protects a ruptured drum sealing it with a clot and subsequently healing proceeds A copious flow of cerebrospinal fluid from the ear lowers the intracranial pressure and thus becomes a decompressive agent The hazard of otitis media or impending meningitis prohibits irrigation A complicating otitis media should receive conservative treatment Exceptionally mastoiditis requires operation Fatal hemorrhage from the ear is very rare the writer having seen but one case due to rupture of the jugular bulb

The degree of increased intracranial tension in cerebral edema and contusion depends largely on the brain's fluid content

Dehydration much discussed recently as a therapeutic measure following brain injury is secured in three ways by means of (a) a limitation of the fluid intake (b) hypertonic solutions and (c) lumbar puncture

(a) The fluid intake should be limited to from 600 to 1200 cc or less for the first few days and subsequently restricted for several weeks

(b) Hypertonic solutions of glucose or sucrose have come into general use The former a food providing prophylaxis against acidosis has a dehydrating effect which lasts from three to six hours The latter being a disaccharide cannot be utilized as a food in the blood stream but produces a more last-

ing dehydrating effect frequently for twelve hours Hypertonic solution of sucrose is a powerful diuretic No fixed rule can be made relative to the concentration frequency or amount of hypertonic treatment Customarily 50 to 100 cc of a 10 per cent solution of glucose or sucrose is administered intravenously and repeated at intervals of from six to twelve hours Vigorous dehydration with hypertonic glucose solution causes a short initial rise followed by a secondary fall and a tertiary increase in cerebrospinal fluid pressure To obtain the desired secondary fall in pressure one must be prepared for a possible subsequent rise Thus clinically when injections of hypertonic glucose solution are discontinued and fluid by mouth is substituted there follows a temporary exacerbation of symptoms A secondary rise of cerebrospinal fluid pressure does not follow the use of hypertonic sucrose solution For this reason sucrose has replaced glucose when a dehydrating effect alone is desired Renal damage especially in elderly persons may result from its overuse

Magnesium sulfate given orally an ounce on several successive mornings promotes dehydration In an unconscious patient a 6 ounce retention enema of a 50 per cent magnesium sulfate solution is helpful It may be repeated in three hours but is seldom effective after that The skin should not be allowed to become dry and parched Dehydration must be carefully watched for it is easily overdone unwelcome consequences include secondary bleeding and hyperpnea which may be fatal

(c) Removal of cerebrospinal fluid by lumbar puncture permits the entrance of more arterial blood and increased oxygenation of the brain removal of interstitial fluid favors a greater volume of both blood and cerebrospinal fluid (For a more detailed discussion see the section on Spinal Fluid)

Operative procedures are confined largely to the evacuation of clots the removal of indurated fragments or missiles and the correction of depressed fractures Some patients with cerebral edema who have not responded to various forms of dehydration are benefited by subtemporal decompression with drainage This is especially true of wet brains

The cerebral congestion incident to alcoholic intoxication complicates convalescence from brain injury. Whenever syphilis is suspected of retarding recovery, a Wassermann test makes the situation clear, and appropriate treatment is indicated.

Epidural Hemorrhage (Extradural, interval)—A linear fracture which crosses a meningeal groove in the temporal bone may produce an epidural hemorrhage (Fig. 131). The history is characteristic, and a diagnosis can frequently be made from that alone. The patient usually rendered unconscious by the initial blow recovers consciousness for a time and then again lapses into coma. The period of consciousness, called the "free

plete, Jacksonian convulsions, beginning in the face or arm, are frequent. Bradycardia, increasing blood pressure and Cheyne-Stokes respiration may accompany the second period of unconsciousness. Frequently the pupils are unequal, the larger located on the side of the hemorrhage. Generally the deep reflexes on the hemiplegic side are increased, the Babinski sign is positive and ankle clonus is present. The spinal fluid, usually under increased pressure, theoretically should be clear, but at times oozing into the subdural spaces gives a bloody tinge. An epidural clot forming over a silent area may be overlooked, and fulminating types are known in which death occurs before sur-

Fig. 131—Linear fracture crossing the meningeal groove, a frequent cause of extradural hemorrhage

interval," varies from minutes to hours, rarely lasting several days. During this interval the patient may have headache and tenderness on the side of the hemorrhage attributable to separation of the dura from the inner table of the skull. Slow but massive bleeding gives signs of contralateral motor weakness. Usually this begins in the face, extends to the upper and finally to the lower extremity and is due to encroachment of the enlarging clot on the motor cortex. Attention is again called to the difference between this type of slowly developing hemiparesis and the rapid hemiplegia resulting from extensive cortical contusion or laceration. In the latter the hemiplegia is not only sudden but usually flaccid and more com-

plete. Jacksonian convulsions, beginning in the face or arm, are frequent. Bradycardia, increasing blood pressure and Cheyne-Stokes respiration may accompany the second period of unconsciousness. Frequently the pupils are unequal, the larger located on the side of the hemorrhage. Generally the deep reflexes on the hemiplegic side are increased, the Babinski sign is positive and ankle clonus is present. The spinal fluid, usually under increased pressure, theoretically should be clear, but at times oozing into the subdural spaces gives a bloody tinge. An epidural clot forming over a silent area may be overlooked, and fulminating types are known in which death occurs before sur-

gical treatment can be instituted. As a rule, however, the clot is disclosed by subtemporal exploration, its removal accomplished and the bleeding controlled (Fig. 132). Subdural hemorrhage results if the meningeal vessels are torn on the under-surface of the dura. More frequently it is secondary to subarachnoid bleeding. Although located predominantly over the parietal or temporal lobes, it may appear elsewhere. Clinically, it closely resembles epidural hemorrhage. The signs and symptoms, however, are usually more fulminating, and the "free interval" may be absent. The clot varies from a mere film to a coagulum several centimeters thick. It is dark and of currant-jelly consistency. Although the clot is easily washed

from the subdural space operation proves less effective than in the epidural type because of the rapidity of the bleeding.

Subarachnoid hemorrhage presents no characteristic clinical picture and may be small or extensive. When blood seeps into the subdural space stiffness of the neck on flexion develops but there is little restriction on rotation phenomena due to meningeal irritation by free blood. The neck is stiffer whenever the fluid is under increased tension. A bilateral positive Kernig sign is present. These patients usually comatose may show many of the signs and symptoms described under contusion (Fig 124)

as decerebrate rigidity. The entire body is stiff the arms are extended and rotated in ward with the wrists flexed and the rigid legs are extended with pronation of the feet. This attitude designated the flapper position resembles the figure of a seal. The clinical course marked by sweating a rapid pulse hyperthermia and Cheyne Stokes breathing, often ends fatally (Fig 125).

Chronic subdural hematoma (pachymeningitis haemorrhagica interna traumatica or encapsulated subdural hemorrhage) is a distinct entity. It may appear at any age. Cases have been seen in patients from seven to ninety years of age. The preliminary in

Fig 132—Massive epidural hemorrhage. The dura has been well separated from the inner table of the skull.

Subcortical hemorrhages possible anywhere in the brain substance are frequent at the junction of the gray and white matter. In size they vary from a few millimeters to 5 cm or more. In the region of the motor area or internal capsule they cause contralateral alternating hemiplegia. Such hemorrhages indicate brain injury, always severe and often fatal. Occasionally it is possible to explore and remove large subcortical clots; more often they are not amenable to surgical treatment. Hemorrhages into the midbrain or brain stem are generally referable to fracture of the middle or posterior fossa. They give a characteristic picture known

perhaps trivial and forgotten may have been no more than a lump on the head or a playful blow in a game. Often it follows severe injuries involving fracture of the skull. Hemorrhage progresses slowly, usually weeks or even months pass before major symptoms appear. It is often confused with brain tumor as clinically it suggests a gradually increasing intracranial pressure. The symptoms are irregular in progression variability being one of the chief characteristics. Headache intermittent but growing in both severity and frequency, an outstanding complaint may be greater on the side of the lesion. Nausea and vomiting

occur vision is disturbed and the disks are frequently choked. Restlessness, perversity, negativism and untidiness are familiar and conspicuous features. Mental aberrations provide the excuse for committing such patients to asylums.

Localizing signs are few. Occasionally jacksonian convulsions, homonymous hemianopsia, aphasia or mild degrees of motor weakness occur. Increased contralateral deep reflexes and a positive Babinski sign may be found. *The percussion note over the calvarium is frequently heightened on the side of the hematoma.* If anisocoria exists the larger pupil is on the side of the lesion. The spinal fluid under increased pressure is at times xanthochromic with its globulin content augmented. In late cases the fluid may return to normal in all respects.

The hematoma usually unilateral, seldom bilateral, may attain an enormous size covering the entire frontal with part of the parietal or temporal lobe. It is surrounded by a neomembrane having an opaque outer and translucent inner surface. The outer membrane attached to the undersurface of the dura has a reddish brown appearance resembling the surface of the liver. It consists of organizing granulation tissue containing large mesothelial like spaces. The thin translucent inner membrane covered by mesothelium is freely movable over the arachnoid. The hemorrhage is venous coming from pial vessels or longitudinal sinus radicals. Bilateral hematomas may follow rupture of these radicals. The contents of the sac vary. Early cases show uncoagulated blood or black clots floating in dark green fluid. As the clots disappear the fluid becomes xanthochromic. In long standing cases the fluid content may be clear as water. Some small hematomas perhaps absorb spontaneously but the majority terminate fatally unless relieved by operation.

Treatment—Ventriculography localizes the lesion when clinical methods fail. Treatment is accomplished in one of three ways: (1) emptying and removal of the sac by an osteoplastic approach, (2) evacuation and partial removal of the membranes by subtemporal decompression, (3) washing out the contents through multiple trephine openings. The membranes need not be removed.

Subdural Hydroma (meningitis serosa, circumscripta, traumatic serous meningitis)—After certain injuries the ruptured arachnoid membrane allows the cerebrospinal fluid to escape into the subdural space where it cannot be absorbed. This may take an acute or chronic form. In the former the fluid is free; in the latter it becomes encapsulated by a thin translucent membrane. Virchow may have had this in mind in describing hydroma of the dura. Its symptomatology is almost identical with that of chronic subdural hematoma. A large pocket near the motor strip will cause contralateral hemiparesis or hemiplegia. In acute cases exploration reveals a sweating arachnoid with an excess of fluid pocketed between the sulci. The fluid spurts when the dura is opened and postoperatively drains for several days. In chronic cases one encounters a sac of clear fluid surrounded by a thin membrane. The condition occurs less frequently than chronic subdural hematoma. Favorable results follow operation.

Traumatic pneumocephalus (intracranial pneumatocele or serocele)—a condition signifying the presence of air in the intracranial cavity, occasionally follows a skull fracture which communicates with one of the paranasal or mastoid sinuses. This creates a portal of entrance for air which may occupy the ventricles, subarachnoid or subdural spaces or even penetrate the brain substance. The air may enter immediately but more often its entrance is delayed for days, possibly weeks. The fracture usually crosses the posterior wall of a frontal sinus or the cribriform plate. The subjacent dura being torn and the frontal lobe softened a direct route is provided for the passage of air into the intracranial chamber. Coughing, sneezing or anything which raises the pressure in the paranasal sinuses above the existing intracranial pressure brings this about. Cerebrospinal rhinorrhea is frequently present. The air is most often pocketed in the frontal lobe. Entrance of the air causes terrific headache. Roentgenograms graphically show the air. Sometimes the patient shows irritability or disorientation or is subject to delusions. Strangely the fistulous passage exhibits now and then a ball valve action, freely admitting air but blocking its escape. A comparable situation occasionally follows when a

fracture communicates with the mastoid cells. Roentgenograms should be frequently repeated to ascertain whether the air is increasing or absorbing.

Evidences of meningeal irritation such as stiffness of the neck, retraction of the head and a positive Kernig sign at times appear. The cerebrospinal fluid may be under increased pressure, the cell count augmented and the globulin content above normal. Leukocytosis may exist. Occasionally bacterial meningitis due to staphylococci, streptococci or pneumococci may develop.

Treatment—In approximately 40 per cent of the cases recovery is spontaneous if the patient is kept absolutely recumbent and quiet. He should be cautioned against coughing, sneezing or straining at stool. He should not feed himself. The absorption of air and closure of the fistulous tract will be indicated by the cessation of headache and of cerebrospinal rhinorrhea. In some cases operation is necessary to free the brain of air and to close the rent in the dura. Gratifying results are usually obtained. Recovery has followed operation even in the presence of bacterial meningitis.

Pneumatocoele crani is rare. Here gaseous tumors appear beneath the scalp following skull fractures which communicate with the paranasal sinuses. The favorite location of the air is identified by crepitation of the tissues; it has also been described over the occiput or vertex. As with traumatic pneumocephalus, coughing or sneezing exaggerates the lesion. An appropriate bandage should be put on; occasionally operation is required to close the sinus tract.

Arteriovenous Aneurysm—In approximately 70 per cent of the cases of basal fracture the body of the sphenoid bone is involved. Under such circumstances an abnormal opening or arteriovenous aneurysm between the wall of the internal carotid and the cavernous sinus is not an altogether unexpected complication. This occasions a reversal of the flow of arterial blood into the cavernous sinus. The backflow dilates the cavernous sinus and its communicating veins, particularly the ophthalmic. The aneurysm is usually unilateral, very rarely bilateral and its development is either rapid or slow. Stabbing knife-like pain centered

behind the affected eyeball and accentuated by a change of position may be the initial symptom. Pulsating exophthalmos occurs in most cases (Fig. 133). This together with an audible bruit and a history of head injury is pathognomonic of arteriovenous aneurysm. Dilatation of the veins of the upper lid, forehead and temple occurs. The scleral vessels become greatly engorged; the optic disk becomes choked and vision is affected. In one case of nasal hemianopsia, blindness could be produced temporarily by compression of the jugular veins. Temporal hemianopsia, central scotomata and total blindness have

FIG. 133.—Pulsating exophthalmos secondary to arteriovenous aneurysm complicating a basal skull fracture. The exophthalmos appeared two months after the injury. Note the dilatation of a periorbital vein of the forehead and eye. A distinct bruit was audible.

been described. Limitation of extraocular movements increases with the exophthalmos. Diplopia is frequent. Chemosis and corneal ulceration may occur.

A bruit varying in intensity from a soft murmur to a distressing roar and synchronizing with the pulse is audible to the patient. Perceptible to the naked ear, the sound becomes very loud when a stethoscope is placed over the adjacent temple or eyelid. It can be stopped or greatly diminished by compression of the corresponding common carotid artery. A convincing demonstration of this fact is easily secured when a stethoscope is placed over the upper lid, the tem-

poral pulse felt and the carotid artery compressed. The bruit and temporal pulse disappear simultaneously. Compression of the jugular vein alone temporarily increases both the bruit and the exophthalmos.

Treatment—An arteriovenous aneurysm rarely heals spontaneously. Patients so affected must be quiet. The accepted treatment, ligation of the common or internal carotid, is not without risk as contralateral hemiplegia may result in middle-aged patients. Digital or mechanical compression of the carotid artery should be tried experimentally to determine what effect later ligation is likely to have on the collateral cerebral circulation. Whenever the vessel can be compressed for an hour without causing headache, contralateral weakness or tingling of an extremity, operation is permissible. The safest procedure is primary constriction of the vessel with fasciculi, followed later by complete ligation. Sometimes thrombosed orbital veins must be removed later.

Sequelae—*Convulsive states following head injury*. Convulsions are rare immediately after head injuries when present they are usually general though focal attacks are not unknown. The Jacksonian type usually indicates irritation of the contralateral motor cortex. Its causes include laceration, bleeding, local edema and the presence of embedded foreign bodies. The etiology of general convulsions is less clear. Some patients with a lowered threshold have convulsions from minimal stimuli which ordinarily would not start an attack. The occurrence of decerebrate rigidity soon after an injury is of serious import as it indicates damage to the midbrain or brain stem.

Post traumatic epilepsy describes a state in which convulsions develop after a brain injury. Focal or general the attacks are not infrequently delayed until months or years have passed. Encephalography usually shows areas of cortical atrophy and enlargement of the lateral ventricles. When drawn by scar tissue toward the cortical surface the ventricle is said to be wandering. Dense adhesions deep between the damaged brain tissue and its covering membranes often occur. The cicatrix need not be near the motor area to initiate convulsive attacks. However its proximity to this area to a large extent governs their frequency.

Treatment is unsatisfactory. The attacks to a large extent may be controlled by phenobarbital and the proper regulation of the diet, activity and habits of life. Extensive removal of the scar has been advocated on the assumption that large operative cerebral defects subsequently fill with fluid and prevent new cicatricial formation.

Postconcussional state a term currently used to describe a late train of symptoms following head injuries presents these principal features: headache, dizziness, weakness, vasomotor instability, irritability, memory and dispositional changes, sleeplessness, fear, worry and transient ocular disturbances. The organic and psychogenic factors involved are difficult to differentiate. As might be expected, compensation insurance has brought the psychogenic factor to the front. When it becomes dominant the condition is described as a post traumatic neurosis, traumatic psychoneurosis, psychasthenia or hysteroneurasthenia. It seldom occurs in children.

The intensity of a neurosis bears little relation to the severity of the original trauma. With trivial head injuries patients develop severe neuroses and *vice versa*. Very humanly, some persons exaggerate their symptoms in the hope of increasing their financial reward. A neurosis seldom improves if a law suit is pending. After a satisfactory settlement the psychogenic or intentional part of the symptoms usually clears up leaving the organic basis which may or may not disappear. Such patients are exceedingly difficult to treat. Cooperation of the family and of the employer in providing a suitable occupation goes far toward favoring recovery but unfortunately this is often impossible to secure.

BRAIN ABSCESS

(Suppurative Encephalitis)

The term "brain abscess" usually includes all intracranial abscesses which may be extradural subdural or intracerebral. Extradural abscess is not common but occurs when an inflammatory process of the skull, accessory nasal sinuses middle ear or mastoid is arrested by the dura so that pus accumulates between the bone and the dura. Subdural abscess begins as small areas of circumscribed meningitis but may extend over an entire hemisphere or even over a large part of both hemispheres. Ultimately, if no treatment is instituted the pus breaks through the limiting membrane and a purulent meningitis ensues. Intracerebral abscess may occur in any part of the brain and is usually secondary to inflammation of adjacent structures but the organism may be carried through the blood from a distant point of infection. These abscesses may be single or multiple.

Etiology.—The common etiological factors are (1) osteitis of the skull (2) fractures and gunshot wounds (3) inflammation of the accessory nasal sinuses middle ear or mastoid and (4) septicemia and pyemia sec-

ondary to inflammatory conditions in other parts of the body, particularly of the lungs and pleura.

The organism present varies greatly, but usually one of the common pyogenic types is found in smear or in culture. Gas forming organisms are occasionally found. Their presence is suspected by the escape from the wound caused by a compound skull fracture of thin, foul smelling pus and gas but the presence of the gas may be demonstrated in roentgenograms. In 1938 I reported two such cases with a review of the literature. The roentgenogram in one of these cases is shown in figure 134.

Pathology.—Extradural abscess occurs when thickening of the dura prevents the extension of pus beyond the membrane. As the pus accumulates the dura is separated from the skull. These abscesses are generally sessile. Occasionally the dura may remain attached to the skull except over a small area which slowly bulges into the cranial cavity active proliferation preventing rupture. The result is the formation of an abscess with a firm wall attached to the surrounding dura by a small stalk.

A small extradural accumulation of pus is an important stage in the formation of an intracerebral abscess. During this stage the dum becomes firmly adherent to the parietal and the underlying cerebral cortex is edematous. If the dum become necrotic there is an extension of pus into the edematous cortex followed by supuration. These changes in the meninges ultimately form the abscess stalk connecting the original site of infection with the intracerebral abscess. This therefore is an infection of the brain by direct extension from the primary focus. The direct connection may be absent when the infection has reached the brain through a blood vessel. Irrespective however of whether the infection reaches the brain by direct extension or through the circulation from nearby or distant foci the resultant reaction on the part of the brain is the same. This reaction consists of hyperemia with a varying amount of edema and a local red supuration (Fig. 135). New capillaries are formed in the area with striking rapidity. From the blood vessel walls fibrin casts wander into the field and are most important in the formation of the abscess wall which in the favorable cases entirely encircumvents the inflammatory process (Fig. 136).

Symptomatology.—The signs and symptoms of brain abscess are first those of infection followed later by evidence of increased intracranial pressure. Headache is a very constant complaint and though it may be intermittent, is present in all stages. Vomiting is associated with the headache but varies with the degree of increased intracranial pressure except in the case of a cerebellar abscess in which it occurs as an

early irritative sign. The pulse rate during the early period is usually rapid but is almost invariably slow after the encapsulation of the abscess. Convulsive seizures are fre-

quently observed. The temperature range is likewise high during the first stage and low during the second. In the beginning cerebri-
tion is slow and there is gradually increasing

Fig 131—Lateral view of the skull showing a small depressed fragment of bone (full thickness of skull) at A and a small large bubble of gas at B in an underlying abscess of the parietal lobe

quent in the early period and may occur at any stage. They may be focal or general in type depending on the site of the lesion. The optic disks may show slight changes as

stupor leading to coma in the second stage. Delirium seldom occurs unless there is associated meningeal inflammation.

The clinical course of the disease there-

Fig 133—Supratentorial encephalitis before the period of abscess wall formation

a result of cerebral edema in the early stage. In later stages a high grade choked disk with hemorrhages is the rule. Leukocytosis is present but disappears after complete en-

cephalitis. The disease may be divided into three stages: first, diffuse infection involving a limited area of the brain or brain and meninges with evidences of systemic infection—eleva-

tion of temperature rapid pulse and leukocytosis with or without focal neurological signs Headache and vomiting and frequently muscle twitchings and even convulsive seizures may occur The optic disks show little or no change Following the invasion the infection may spread rapidly through the brain or meninges or may be encapsulated The second stage that of encapsulation is afebrile and without other evidence of systemic infection Signs of increased intracranial pressure headache vomiting slow pulse choked disk and stupor with or without localizing signs depending on the location of the abscess characterize this stage In the third or terminal stage the abscess if untreated produces fatal

clinical evidence is in favor of a brain abscess and is only performed when there is reason to believe the inflammation is meningeal Serous meningitis can usually be differentiated from abscess by the absence of severe pressure symptoms in spite of an extreme degree of choked disk with impairment of vision The reason for the absence of pressure symptoms in cases of serous meningitis has never been satisfactorily explained but it is a fact that the patient does not have headaches in spite of the high cerebrospinal fluid pressure choked disk and loss of vision

Infective sinus thrombosis is characterized by intermittent fever chills general malaise prostration rapid pulse and restlessness

Fig 136—A completely encapsulated brain abscess Death resulted from increasing intracranial pressure

pressure symptoms or the capsule ruptures with the escape of pus into the meninges ventricles or brain substance After the rupture the course is again a febrile one

Differential Diagnosis—The initial course of a brain abscess may be so similar to that of purulent meningitis that differentiation is often impossible during the first few days However the progress of symptoms in meningitis is much more rapid than in brain abscess In meningitis irritative signs predominate while even in the early stage of an abscess the cerebral edema in the neighborhood of the infection will probably produce some signs of pressure and as the condition approaches the second stage the pressure signs become much more marked Lumbar puncture should be avoided if the

During the afebrile phase the symptoms are slight or entirely absent Lumbar puncture and a Queckenstedt test may be necessary Gradenigo's syndrome is characteristic and should not be confused

Only the second stage of an abscess can be confused with that of a brain tumor The progress of symptoms in the case of an abscess is often much more rapid than in the case of a tumor A patient with a brain abscess usually gives a history of cerebral trauma or a primary focus of infection A ventriculogram may be necessary but is not without danger because of the tendency of abscesses to rupture into the ventricle or subarachnoid space

The history of recent trauma may make a differentiation between hemorrhage and

abscess necessary. Subdural hematoma with pressure symptoms some weeks after cerebral trauma may be very confusing. One must depend on the history and progress of symptoms but needle exploration through a small opening of the suspected area may be necessary.

Treatment—The sulfa drugs and penicillin are now valuable adjuncts in the treatment of brain abscess. The use of these drugs however has not greatly changed the incidence of brain abscess for in the course of infections of the ears, mastoids and accessory nasal sinuses and in osteomyelitis of the skull brain abscess develops in spite of the employment of these new drugs in treating the primary infection. Likewise metastatic abscesses of the brain still occur as the result of blood borne organisms particularly in suppurative lesions of the chest cavity. The use of the drugs in open wounds of the skull has doubtless diminished the number of brain abscesses following skull trauma. The work of Pileher demonstrates however that care must be exercised in the use of these drugs within the cranium as they produce a certain amount of irritation. It is very improbable that the drugs have any influence upon the growth of organisms within the capsule of well walled off abscesses but in the early stage when the infection is diffuse or in any stage when there is spread to the meninges their value has been well demonstrated.

In spite of drugs abscesses must be allowed to encapsulate and then must be drained. Drainage can be accomplished through an opening 1 to 1.5 cm in diameter. Care should be exercised to avoid undue traumatization of the abscess wall. Through the opening a small blunt pointed cannula is passed in a search for the abscess. If pus is found the needle should be immediately withdrawn so that drains can be inserted into the distended cavity. The type of drainage material varies but most operators prefer one or more small rubber tubes. Two ordinary thin walled Carrel tubes which have been split along their entire length and made pointed at the end can be seized in a small bayonet forceps and pushed gently into the cavity. Pus will exude through and around the tubes and the cavity will be slowly evacuated. The tubes will remain in position without sutures. The skin wound is small and should not be sutured. The tubes should project about 1 cm from the outer surface of the wound and the dressings should be placed around these projecting ends thus avoiding pressure of the overlying dressings. If tubes are properly placed in the cavity and care is exercised in the dressing they will remain in place

until the suppuration ceases which may be several weeks. They are gradually shortened after the first four weeks by cutting a few millimeters from the outer end of the tube. By this method there is a minimum scar at the site of the abscess.

Mosher for many years has successfully used a wire gauze mesh tube. King advised unroofing the abscess by removing the bone and cortex overlying it. Danly prefers a simple aspiration on which it is necessary one or more aspirations being necessary.

Complete removal of the abscess is possible only in exceptional cases and should not be undertaken as a routine measure.

Prognosis—The prognosis in a case of brain abscess depends on the location of the lesion and the type and virulence of the causative organism. Multiple abscesses are uncommon and very difficult to cure. Abscess of the temporal lobe secondary to otitis media is the most favorable while abscess in the frontal lobe offer a greater problem in drainage and are less favorable. Cerebellar abscesses drain well but the rapid progress of the condition often produces serious and even fatal disturbance of the brain stem before encapsulation occurs. Deep seated abscesses are often difficult to drain offering a poor prognosis. A superficial lesion at the site of a depressed fracture is favorable because proliferation of the indurated remnants of the dura often produces firm encapsulation. Intracranial extension of infection in osteomyelitis of the skull still remains a serious lesion in spite of the favorable influence of sulfa drugs and penicillin.

TUMORS OF THE BRAIN

Tumors of the brain which for practical purposes include all intracranial new growths are far more common than is generally realized. They constitute nearly 2 per cent of all tumors found at operation or autopsy. It is seldom realized that tumors of the brain are much more common than cancer of the stomach and that the prognosis on the whole is better. In fact many intracranial new growths can be treated by modern neurosurgical methods more successfully than can most of the tumors found elsewhere. Early diagnosis will greatly increase this favorable percentage.

Brain tumors may be roughly classified as follows: those arising from the coverings of the brain such as the dural meningioma; those developing in or on the cranial nerves best exemplified by the acoustic neuroma and the optic nerve spongioblastoma; and those originating in the brain tissue as the various gliomas, sarcoma, carcinoma, gumma and metastatic lesions.

Symptoms.—The symptomatology is exceedingly variable and depends on a number of factors, the chief of which are the location, extent, rate of growth and type of tumor. The so-called classical symptoms are simply those of increased intracranial pressure and may or may not be related to the factors just listed. These symptoms of slowly increasing intracranial pressure are in the usual order of sequence: headache, nausea, vomiting and visual disturbances. Focal symptoms with or without evidence of increased pressure may be present depending on the location of the tumor. These may consist of jacksonian epileptic attacks, weakness or paralysis. Mental change may be the initial symptom and in a lesion in the

frontal lobe may predominate throughout the course of the disease.

The *headache* is of little localizing value in the case of a cerebral tumor but in a cerebellar lesion the headache is predominantly low occipital. There may be also frontal headache associated with the pain at the back of the head and upper part of the neck. A tumor above the tentorium irrespective of its location frequently produces bilateral frontal headache. The pain accompanying a parietal or temporal lobe tumor occurs somewhat more frequently on the side of the lesion but the incidence is not sufficiently high to be of definite localizing value. The headache is usually described as dull throbbing in character lasting for hours and occurring almost daily. Some patients complain of practically continuous headache which varies in intensity. Bending over or exertion may greatly intensify the pain. As a rule the headache is not relieved by vomiting.

Nausea and vomiting are comparatively late manifestations of a brain tumor and always indicate an increase in the intracranial pressure. These gastric symptoms when not easily explained otherwise should always raise the suspicion of an intracranial tumor. This is particularly true in children in whom nausea and vomiting lasting more than two or three days is almost always due to increased intracranial pressure. It is surprising how frequently this possibility is overlooked and the tonsils and appendix although otherwise symptom free are removed in the hope of giving relief. Nausea may not be followed by vomiting in the early cases but as the pressure increases vomiting without nausea is frequently noted. At first there is no distinction between vomiting due to increased intracranial pressure and that from other causes but later it may appear without warning and become so forceful that a diagnosis of increased intracranial pressure can be made. This latter type of vomiting is spoken of as projectile and not infrequently the expulsive force is so great and appears with such suddenness that the vomitus will be thrown a distance of several feet sometimes to the great embarrassment of the patient. It must be emphasized however that projectile vomiting is a relatively late symptom.

vomiting is frequently associated with brain tumors

Visual disturbances are of two types a general diminution in visual acuity and a loss in some part of the visual field. The first is the result of increased intracranial pressure causing edema of the optic nerve head from partial venous obstruction. As the swelling of the nerve head progresses it is pushed out farther and farther into the eyeball the actual distance being measured in diopters with the ophthalmoscope. The swelling of the nerve head obliterates the normal cup and the resulting appearance has been designated as *choked disk*. The obstruction of venous return may also produce widespread retinal hemorrhages. Visual acuity is not entirely dependent on the number of diopters of swelling but rather on the shape assumed. The mushroom type of choked disk causes early visual loss while the cone-shaped although measured as more diopters of swelling may not seriously interfere with vision. After long continued choking of the disks the swelling gradually disappears leaving a yellowish white disk indicative of secondary optic atrophy. When this appears hopes for much restoration of vision are nil. For this reason alone careful ophthalmologic examinations should be made and repeated at frequent intervals for every patient suspected of having a brain tumor.

Defects in the visual field occur with tumors of the temporal and occipital lobes from pressure on or destruction of the optic radiations and in tumors of the pituitary body or adjacent regions producing direct pressure on the optic nerves or tracts. Pituitary tumors commonly press upward in the midline stretching the crossed fibers of the optic chiasm. This produces blindness in the lateral half of the visual field for each eye and is called bitemporal hemianopsia. Pressure on one of the optic tracts posterior to the chiasm or a tumor in the temporal or occipital pole may produce blindness in the lateral half of the temporal field of one eye and the inner half or nasal field of the opposite eye. This is called an homonymous hemianopsia and the lesion is always located on the side opposite the blindness. This type of blindness is frequently unnoticed until an automobile accident results from failure to see cars approaching from one side.

The *mental symptoms* are usually characterized by a change in personality forgetfulness irritability without evident cause difficulty in concentration somnolence and in the more advanced cases slovenliness some times to the point of complete disregard of the usual personal habits. Many patients show great emotional instability characterized by either undue laughing or crying. Marked facetiousness is a frequent symptom in prefrontal lobe tumors.

Diagnosis—The diagnosis of a brain tumor and even its exact location are not considered sufficient. In addition it is desirable to know preoperatively the type of tumor likely to be encountered so that the best surgical procedure can be planned. It is therefore essential for the neurosurgeon to be familiar with the natural history symptoms and location which to a surprising extent are characteristic of the various intracranial tumors.

Ventriculography is the most valuable single diagnostic aid in the detection and localization of brain tumors at the surgeon's command. Its routine use is not recommended for every case of suspected brain tumor but it should be performed whenever the evidence of such a lesion is rather definite and a positive diagnosis or exact localization cannot be made on the neurological findings and the routine roentgen examination. There is probably a mortality rate of not more than 1 or 2 per cent which can be honestly attributed to this procedure. For a strictly diagnostic procedure this may appear prohibitive. It must be remembered that practically every patient with a brain tumor will die unless he is successfully operated on. Therefore any diagnostic procedure which will be of material value in making possible the successful extirpation of an otherwise hopeless lesion even though there is some risk involved is justifiable.

Two locations for the drill openings are common used. The first is located about 1½ inches above and an equal distance behind the top of the ear. The second is made about 1¼ inches above the occipital ridge and an equal distance from the midline. The writer prefers the lateral approach. In the majority of cases a single trephine opening is sufficient. This is generally made on the right side. The scalp is infiltrated with a local anesthetic and a vertical incision about 2 inches long is made through the scalp aponeurosis and pericranium. The larger blood vessels are caught with

hemostats and a small self retaining mastoid retractor is used to hold the incision apart. The skull is perforated with the Hudson burr and a small incision made in the dura. A ventricular needle is then carefully passed medially into the ventricle. The ependymal lining of the latter offers slight resistance to the passage of the needle generally indicating that the ventricle has been reached and that the obturator can be withdrawn. The normal ventricle lies about 4 or 5 cm. from the scalp. By this lateral approach the ventricle is entered at the junction of the posterior and descending horns with the body of the ventricle. An adapter fitted to a short length of rubber tubing is instantly attached to the ventricular needle, the tubing slipped on to a graduated glass manometer and the pressure of the fluid noted. While this is not an essential part of the technique the data obtained are frequently useful. If the pressure is high the fluid should not be evacuated rapidly. Instead, a small amount of fluid should be allowed to escape, the tubing should then be pinched for a moment and the process repeated. A too rapid reduction in ventricular pressure may cause petechial hemorrhages in the ventricular wall. Air or oxygen is then slowly injected into the ventricle. The writer prefers oxygen because it is more rapidly absorbed. Since using oxygen it has not been necessary to tap the ventricle to relieve rapidly developing pressure symptoms, a common occurrence when air is used. The oxygen is injected in amounts of from 5 to 10 cc., an equal quantity of fluid being withdrawn before each injection. At the completion of the procedure, the intraventricular pressure should be atmospheric. Occasionally it is impossible to withdraw more than 1 or 2 cc. of fluid because of ventricular collapse. In such cases it is justifiable to inject first 3 or 4 cc. of oxygen and then disconnect the syringe allowing fluid to be forced out. Quite satisfactory filling of the ventricles can sometimes be obtained by this method.

The patient's head rests on the occiput with the face upward during the initial filling of the ventricle. When no more fluid can be obtained the occiput is elevated and the head turned from right to left several times. This allows the gas to pass into the third and opposite lateral ventricle. An attempt should always be made to fill one ventricle completely and at least part of the opposite one. Many errors in the interpretation of ventriculograms are due to incomplete filling. The scalp incision is closed in layers and roentgenograms of the head are made in several positions.

Encephalograms are made by the injection of air through a lumbar puncture needle with the patient in a sitting position. By this procedure, the subarachnoid space is filled with air, and obstructions in the cerebrospinal fluid pathways over the cortex and in the various cisternae can be diagnosed in most cases. As a rule, the ventricles are not as well filled as in the previous procedure. Encephalography is a very useful diagnostic aid in the detection and localization of small tumors, especially those involving the cortex.

However, it is a very dangerous procedure in the presence of increased intracranial pressure and should never be used when choking of the optic disks is present.

The determination of the *spinal fluid pressure* by means of a water manometer attached to the lumbar puncture needle may be of considerable value as corroborative evidence toward the diagnosis of a brain tumor. The fluid should never be withdrawn rapidly, as in the ordinary routine lumbar puncture for diagnostic purposes since in the presence of increased intracranial pressure, the tonsils of the cerebellum may already be wedged downward through the foramen magnum, and the sudden relief of pressure from below may cause still further dislocation. This may produce sudden pressure on the medulla with resulting respiratory failure. In the presence of choked disk no fluid should be withdrawn by lumbar puncture. However, at times, chemical examination or a cell count is of great importance, but not more than 5 cc. should be withdrawn for these tests.

TREATMENT

Anesthesia for Intracranial Operations.—The type of anesthetic used for intracranial operations is of the utmost importance. Ether, chloroform, nitrous oxide and ethylene all raise the intracranial pressure and make the operation correspondingly more difficult. The last two also increase bleeding and cause cerebral congestion. Avertin (tribromethylol chloin) and local anesthetics do not have this drawback and certainly are the preferable anesthetics to be used during the removal of brain tumors. Most operations of this type are of relatively long duration and a local anesthetic unless distinctly indicated does not seem desirable either for the patient or the surgeon's equipment. Avertin produces excellent narcosis. There is no preliminary excitement stage and postoperative nausea and vomiting are reduced to a minimum. The incidence of postoperative pneumonia is also greatly reduced. The dose used varies in different clinics from 50 to 150 mg. per kilo of body weight. The author prefers the larger dose except in very debilitated patients and has seen no harm resulting. With the smaller amounts it is frequently necessary to supplement with ether. While the amount of ether required may be relatively small it may be sufficient to produce some increase in intracranial pressure. A local anesthetic used prior to the administration of the avertin is highly recommended by some surgeons and is of benefit in allowing the use of smaller doses of avertin. Occasionally even when 150 mg. per kilo is used supplementary ether anesthesia is required. As a rule, however, this can be discontinued as soon as the osteoplastic flap is reflected.

Supportive Measures During Intracranial Operations.—The continuous administration of normal

salt solution or a per cent glucose during the course of a prolonged intracranial procedure may be of great benefit in preventing shock and certainly lessens the necessity for transfusions either during the operation or immediately thereafter. The salt solution or glucose may be administered intravenously or per rectum. If during the course of the operation the blood pressure suddenly drops from 50 to 100 cc of 50 per cent glucose can be given intravenously with in most cases very satisfactory results. Citrated blood may be administered. Caffeine sodium benzoate administered subcutaneously or intravenously appears to be a useful stimulant and some believe that it helps reduce the intracranial pressure. If these supporting measures do not have the desired effect or if there is undue delay in obtaining blood for transfusion the patient's head may be lowered but this definitely increases venous bleeding and should be resorted to only in dire necessity. It is to minimize venous bleeding that practically

Fig 137—Osteoplastic craniotomy for parietal lobe tumor. The heavy black line is the scalp incision. The broken line represents the bone flap.

all intracranial operations are performed with the head at a higher level than the body. This reduction in venous pressure has led some neurosurgeons to advocate the sitting position for all cerebellar operations.

General Principles of Cranial Operations.—Certain general principles in neurosurgical technique are applicable to practically all cranial operations. These are outlining the scalp flap, control of bleeding during the initial incision and after the scalp flap has been completed, the perforation of the skull and the sawing between these perforations, the prevention of bleeding from the bone, dural vessels and great sinuses, opening of the dura, control of cortical vessels, protection of the brain from trauma and incision of the cortex.

All scalp incisions should first be outlined with a scratch mark before the operative site is draped since the latter may hide important landmarks. Cross scratches at suitable intervals are made along the proposed line of incision so accurate approximation of the

scalp edges may be assured at the completion of the operation. A curve is always preferable to a sharp angle since the blood supply may be impaired by the latter. Even in curved incisions there is sometimes slight sloughing at the corners of the scalp flap. The base of the flap is usually much smaller than the upper portion but it should be sufficiently wide to insure adequate blood supply. When possible, the base should be so placed as to include a large vessel such as the temporal artery. Ordinarily the base of the flap is made just above or in front of the ear. This not only insures an adequate blood supply but the bone is broken where it is relatively thin. The bone flap is usually hinged by the temporal muscle.

Hemostasis during the initial incision is best accomplished by digital compression. One or two assistants place their finger tips close to each side of the scratch mark and maintain firm pressure as the incision is carried entirely through the scalp. Fine-pointed hemostats are placed on the edge of the galea at frequent intervals usually from 1 to 2 cm apart. These are reflected to either side rolling the galea against the cut edge of the scalp thus compressing the small vessels. Hemostats are never placed directly on the scalp since it is easily crushed and subsequent healing might be dangerously delayed. A gauze sponge is laid along the edge of the scalp and the hemostats are laid over this and then tied together in groups of four or five. Usually a towel is draped over the hemostats to keep them in place during the course of the intracranial procedure. Instead of hemostats a special large skin clip can be used approximating the galea and the upper surface of the scalp. These are especially useful on the flap.

The **scalp flap** including the pericranium is carefully stripped from the bone and turned downward at the base. However the attachment of the temporal muscle is not loosened. Removing the pericranium from the bone flap does not seriously impair the nutrition of the latter but does materially reduce bleeding from the bone. This is a very important factor since slow bleeding from minute points on the inner side of the bone flap is sometimes a very serious postoperative complication. Small bleeding points on the inner surface of the pericranium and larger vessels on the edge of the scalp may be gently desiccated with the electric current. Care should be exercised to shrink only the vessel at its bleeding point and not damage the adjacent tissue.

The **skull** is usually perforated with a Hudson burr using a hand brace. Some prefer an electrically driven drill but the latter is not much faster except in a very thick skull. The author prefers a diamond shaped tip for the initial perforation the drill opening being enlarged by the second and third size Hudson burrs. The fourth size is scarcely ever used. Bleeding from the bone is controlled with Horsley's bone wax. This is pressed into the bleeding points and the excess scraped away with a penosteal elevator or wiped away with gauze. Small bleeding points on the dura may be desiccated with the electric current or temporarily controlled with a cotton pledget. After the entire series of drill openings has been made the dura is carefully freed from the bone about each opening and a Gigli saw carrier which also acts as a dural protector is passed between two holes. A Gigli saw is drawn through

and the bone cut on a bevel slanting outward. Frequent irrigation with salt solution facilitates cutting and keeps the saw cool. Bleeding from a saw cut cannot be controlled until after the osteoplastic flap has been reflected. For this reason a known vascular area in the skull is cut last. To facilitate breaking the bone at the base, a narrow channel may be cut for a centimeter or two medially between each of the lower two drill openings. This channel may be cut with very narrow bladed rongeurs or with a DeVillars forceps. The author prefers passing the high saw guide between the two drill openings and cutting a groove in the inner surface of the bone. This can be readily done without damaging the overlying temporal muscle by holding the saw nearly horizontal. No attempt is made to divide the bone completely, a comparatively shallow groove being sufficient. Flat elevators are placed through the two upper drill openings and the bone flap pried upward until it fractures across the bone. All bleeding points on the bone edges are controlled with wax. Bleeding from the under surface of the bone may be quite marked and is controlled by wiping wax into the small perforations and along the channels of the middle meningeal artery. Control of these bleeding points is often facilitated by desiccating them with a much stronger current than is used on the scalp or dura. The bone flap is then covered with gauze to prevent the bone from becoming unduly dry.

Small bleeding points on the surface of the dura are easily controlled by light desiccation. The middle meningeal artery is divided near the base of the flap and silver clips are applied to the cut ends. Bleeding from large pachionian granulations and from the great sinuses may be controlled by delicate coagulation. Frequently, however, this is not sufficient and thin pieces of crushed muscle should be used. There is considerable danger of rupturing a sinus when attempting to desiccate it. There is also the danger of too great thrombosis with blockage of the sinus. For these reasons it is believed that application of small muscle grafts is preferable. These are firmly pressed against the bleeding points usually by a piece of moist cotton. After a few minutes the muscle will adhere quite strongly to the surface of the dura or sinus. Occasionally it is necessary to divide one of the great sinuses such as the superior longitudinal or the lateral. An unusual difficulty at once presents itself as these large vessels are held open by traction in three directions. In the case of the superior longitudinal the dura pulls laterally on both sides and the falx pulls it downward. When it is necessary to divide such a sinus the dura is opened on both sides up to the vessel. A hemostat can then be placed across the vessel and adjacent portion of the falx or in the case of the lateral sinus onto the tentorium. Division is made between the two hemostats. The vessels can then be closed by a continuous suture of fine silk or the falx can be cut close to and parallel with the sinus and the vein then ligated in the ordinary manner. Occasionally a plug of muscle can be forced into a small opening in the sinus without ligation of the vessel and with the possibility that its lumen will not be completely obliterated. The large veins in the falx and tentorium as well as those encountered in the dura lateral to the longitudinal sinus are most readily controlled by cutting the dura and applying silver clips to all bleeding points. In case one

does not wish to cut the dura or its extensions the large veins may be controlled by very gentle desiccation using a ball tip and a light current. Muscle grafts may also be used.

The dura is opened in the following manner. A small sharp hook is caught into the dura and the latter elevated. Incision is made through the dura as it is held away from the underlying cortex. It is then grasped

Fig. 138—The approach used for a cerebellar tumor

Fig. 139—The approach used for an acoustic neurinoma

with fine-toothed thumb forceps and held up as the dura flap is cut with round-pointed scissors. Many surgeons prefer passing a grooved director through the initial opening and then cutting along the grooved director with a sharp knife. This can be done very rapidly the director being moved forward with the knife held stationary against it. The flap of dura may be turned in any direction but preferably anteriorly or posteriorly as this allows for decompression in-

teriorly, that is beneath the temporal muscle and the control of the superior dural veins with silver clips.

The cortex must be handled with greatest care. Gauze sponges should never be used. Cotton pledgets are used for sponging and many prefer these moistened in saline. Small bleeding vessels of the cortex may frequently be controlled by light pressure with a cotton

Fig 140—Approach for pituitary, suprasellar and frontal lobe tumors

Fig 141—Lateral view of the approach shown in figure 140

pledget. They also may be desiccated using a very light current so as not to shrink surrounding tissue. Occasionally a small muscle graft may be necessary. Silver clips are applied only to cortical vessels which are to be divided. The brain should be kept moist at all times. This can be accomplished by protecting the brain beyond the tumor with moistened strips of sheet cotton. Frequent irrigations of the exposed brain with

normal salt or Ringer's solution is advisable. Incisions whenever possible should be placed so as not to cross large cortical vessels. Vessels which must be divided no matter how small should first be either desiccated or ligated with fine silk, carried on a curved needle or crushed with silver clips. Subcortical vessels are generally controlled with silver clips. Incision through the cortex and deeper layers of the brain may be made either with a scalpel or an electric knife. The writer prefers the latter. When a considerable area of cortex has to be excised to expose a tumor adequately the electric loop is especially useful. With this instrument, long thin strips of brain tissue may be removed rapidly and with a minimum of bleeding. The current must be adjusted for the particular type of tissue being cut. Very edematous or softened brain requires considerably greater dehydration.

Two methods of exposing a deeply situated tumor are commonly used. The first consists of a single incision carried through all layers down to the tumor with careful retraction of the cut edges. The second and probably preferable method except in the Rolandic area is to uncap the tumor by removal of cortex and deeper portions of the brain over a sufficiently large area to give adequate exposure. Occasionally a tumor can be best treated by excising a lobe of the brain. This is comparatively simple in the frontal region as it is necessary only to doubly clip or desiccate and divide the veins passing from the frontal lobe to the longitudinal sinus and dura and to clip the vessels on the surface along the posterior border of the proposed excision. The brain is then incised vertically just anterior to this line and the few deeper vessels are clipped as they are encountered. The occipital pole may be excised in a similar manner. The writer generally prefers removing the temporal lobe piecemeal with the electric loop.

Continuous suction should be available throughout all brain operations. If a small metal sucker is used sponging is rarely necessary and an enormous amount of trauma may be thus prevented. Small bleeding vessels are caught in the end of the sucker and then clipped or the desiccating current may be applied directly to the instrument and coagulation takes place while the field is kept dry. A pledget of moistened cotton placed at the end of the metal sucker will still allow a moderate amount of suction and prevent damage to adjacent brain tissue, choroid plexus or nerves. This use of a cotton pledget is only applicable when the bleeding vessels are very small or when only cerebrospinal fluid is being removed. The small sucker generally used has a diameter of about 2 mm. A slightly larger one (3 mm. lumen) is necessary at times. Very soft brain tumors, as the glioblastomas, may be largely removed by suction. For this purpose a glass tube similar in size to the ordinary drinking tube is very serviceable.

The dura is closed with interrupted fine silk sutures placed about a centimeter apart. It is left open beneath the temporal muscle when a decompression is considered necessary. However, if the dura is infiltrated with tumor cells, as occurs in practically every meningioma and in some gliomas, this portion of the dura must be excised. Various means of repairing the defect have been advocated. Some split the remaining dura into two layers and use the outer layer as a graft over

the defect. Others use a piece of fascia lata. Cargile membrane has also been recommended. The author, after a very extensive experience, now makes no attempt to fill in a dural defect and has seen no harm resulting from contact of the brain with the bone. A pseudodura rapidly forms from wandering cells organizing in the normal dura, and at a subsequent operation it is sometimes difficult to determine which is the original and which the new-formed brain covering. The osteoplastic flap is then returned to position and if the original drill openings were properly placed making a key-stone shaped bone flap and the Gigh saw cuts have been made with the proper bevel, the bone flap will remain securely in position. In the very thin skulls of children or where bone has been rongeuired away to expose a tumor further, one or more steel wires placed through drill openings in the skull and flap may be used to hold it in place. Occasionally the bone flap is completely removed either because it has been extensively involved by the tumor or where a much

The commonest site is along the superior longitudinal sinus, but they may develop on any portion of the dura, falx or tentorium. Because of their usually slow, non-infiltrative growth, the brain is slowly indented. The first symptom of the very common parasagittal meningioma is often sensory or motor jacksonian attacks, starting in the leg, since this cortical area is nearest the midline. This may be followed by weakness of the leg, arm and face in order. Generalized epilepsy is frequent with all types of meningioma. Because the growth is slow and there is usually no block of the ventricular system, intracranial pressure does not increase until edema of the brain develops from interfer-

Fig. 142—Hyperostosis from meningioma of tuberculum sellae

greater decompression is considered necessary than would be obtained by a subtemporal decompression. Under such circumstances the dura is only covered with the scalp flap. The incision is closed by careful painstaking approximation of the edges of the galea using fine silk sutures placed about 1 cm apart. The scalp is then closed with interrupted silk sutures.

MEINGIOMIA

The meningiomas represent about 13 per cent of intracranial tumors. Though ordinarily benign they may become sarcomatous and display a tendency to rapid recurrence. These tumors take their origin from arachnoidal cell clusters and so are most frequent in those areas where the arachnoidal granulations are most abundant.

The meningioma is a tumor of adult life.

ence with the venous return. Consequently choked disk is generally a late sign.

Meningiomas may arise from the cribriform plate producing the syndrome of the olfactory groove. This consists of anosmia and primary optic atrophy, perhaps associated with mental symptoms from frontal lobe involvement. The sella may be normal, but the roentgenogram frequently reveals an enostosis just posterior to the cribriform plate.

Meningiomas of the sphenoidal ridge tend to be flat and produce marked bony overgrowth. The symptoms usually indicate a temporal lobe tumor. A unilateral exophthalmos with swelling of the temporal region may occur. Meningioma of the tuberculum

cellae may be suspected when intemporal hemianopsia and primary atrophy are noted and the roentgenogram reveals a normal sella. Meningioma is uncommon in the posterior fossa.

Meningiomas are fairly frequently calcified but more important is the bony change in the overlying skull. This may consist of a markedly vascular erosion. The flat spreading type of meningioma tends to produce marked bony overgrowth with formation of enostoses or diffuse thickening. A unilateral enlargement of the groove for the middle meningeal artery suggests the presence of an underlying tumor.

The commonest type of meningioma has a tough connective tissue capsule over which course many blood vessels. The tumor is usually adherent to the overlying dura. It may deeply indent but rarely infiltrates the brain substance. Incision into the tumor reveals a firm granular grayish tissue that is sometimes extremely vascular. Microscopically characteristic are cells with abundant cytoplasm massed into whorls. The central cells of the whorls may undergo hyaline degeneration and become calcified producing the psammoma bodies.

Complete excision of the tumor and the infiltrated dura and bone is indicated in practically all cases. The tumor may be removed intact or excised piecemeal with the electric loop. The prognosis is usually favorable.

ACOUSTIC NEURINOMA

The acoustic neurinoma is a slow growing encapsulated tumor arising from the neurolemma of the vestibular portion of the eighth nerve within the porus acusticus. As it expands medially it reaches the cerebellopontine angle and produces a typical syndrome namely unilateral cerebellar involvement with homolateral cranial nerve palsies from the fifth nerve downward.

The first symptom is tinnitus which is followed by progressive loss of hearing. As the fifth nerve is encroached on there develops a loss of the corneal reflex. Later pain characteristic of the doloureux and numbness of the face may appear. As the seventh nerve is stretched a slight peripheral type of facial palsy may be demonstrable. Later disturbance in swallowing and unilateral laryngeal paralysis develop owing to vagus

involvement. Only when the tumor is large enough to obstruct the flow of cerebrospinal fluid does choked disk appear. In the early stages of the tumor tinnitus, loss of hearing, and dizziness suggest Meniere's disease. Pontine tumors with unilateral cranial nerve palsies may cause difficulty in diagnosis. Choked disk is usually absent here and when a third nerve palsy appears acute neurinoma is ruled out. Meningiomas in the region of the cerebellopontine angle may suggest acoustic tumor but the surgical approach is the same for both. A sign pathognomonic of acoustic neurinoma is unilateral enlargement of the porus acusticus as demonstrated by the roentgenogram.

The surgical procedure and the gross appearance of the tumor are described with the technique of unilateral cerebellar exposure for acoustic neurinomas and other angle tumors.

Microscopically the acoustic neurinomas consist of two main cell types (Anlon): 1. Spindle cells arranged in whorls with frequent parallel alignment of the nuclei; these areas are very rich in fibrillae which can be readily stained by reticulum connective tissue stains (Pridien Mallory). 2. Reticulated tissue showing a vascular protoplasmic network containing round and oval nuclei of various sizes. Secondary degenerative changes are very common in the neurinomas as hyalinization, fatty degeneration and at times a psammomatous degeneration sometimes leading to cyst formation.

The prognosis is good if extirpation is complete.

GLIOMA

The gliomas represent over 40 per cent of all brain tumors. They have been classified histologically into ten groups by Bailey, the more common of which produce syndromes. The more common gliomas are the medulloblastoma, the astrocytoma, the glioblastoma, the ependymoma and the oligodendroglioma.

Medulloblastoma—The name "medulloblastoma" was given by Bailey in 1923 to a group of gliomas arising almost invariably in the roof of the fourth ventricle. They occur most frequently in children between the ages of eight and twelve rarely in adults. The tumor, because of its rapid growth and position within the fourth ventricle quickly obstructs the outflow of cerebrospinal fluid.

The symptoms may consequently develop with great rapidity.

Symptoms—The earliest symptom is usually difficulty in walking and a growing tendency to stumble and fall. The child walks with a wide base. Headaches, nausea and vomiting soon follow or may even precede the difficulties in locomotion. Soon the child staggers and reels and walking unassisted may be impossible. Early dimness of vision is noted. The ataxia is ordinarily more marked in the legs than in the upper extremities. Choked disk develops early and is often of the rube type with multiple small hemorrhages at the margin.

Microscopically the tumor consists of groups of cells resembling lymphosarcoma with a deep staining nucleus and little cytoplasm. The medulloblastoma cell has a tendency to spread through the subarachnoid space and set up implantation metastases. Consequently the entire cerebro-spinal axis is irradiated postoperatively. Unfortunately however within two years the tumor usually becomes refractive to x-rays and death results. A few patients have lived for five years.

Astrocytoma—The astrocytomas are the commonest of the gliomas. Clinically they may be divided into three groups: (1) the

Fig. 113—Calcified glioma

Pathology—The appearance of a medulloblastoma at operation is quite characteristic. The vermis is broader than normal and when the tonsils are separated a grayish tumor is seen extending from the fourth ventricle. When the vermis is incised the tumor is found to fill the fourth ventricle more or less completely though frequently only infiltrates the roof. The tumor is usually soft and may be quite vascular. Complete excision is rarely possible and the present practice is to excise only sufficient tumor to establish ventricular drainage. A large cerebellar decompression is made and later x-ray therapy administered. It is the most radiosensitive of all the gliomas.

cystic astrocytoma of the cerebellum usually manifesting itself in childhood; (2) the cystic astrocytoma of the cerebral hemisphere frequently calcified appearing in adult life; and (3) the infiltrating often rapidly growing astrocytoma of children and young adults which sometimes invades both cerebral hemispheres.

The cerebellar astrocytoma of childhood is a slow growing relatively benign lesion and constitutes about 50 per cent of the total tentorial tumors in children. It usually develops in one hemisphere and only rarely crosses the midline. The increase in intracranial pressure due to obstructive hydrocephalus usually manifests itself before the

age of twelve. Consequently separation of the suture lines and convolutional atrophy can be frequently demonstrated in roent-

differential diagnosis usually can be made from medulloblastoma because of the longer duration of symptoms in the astrocytoma

Fig. 144—Astrocytoma of right temporal lobe. The demyelination and deeply infiltrative growth of the tumor are seen.

genograms. Some enlargement of the head with cracked pot sound on percussion may be present. Ataxia and dysmetria signs of cerebellar dysfunction are more marked in the upper extremity than the lower and

Cerebellar astrocytomas in adults are also the most benign of all tumors occurring below the tentorium with the possible exception of the meningiomas and the acoustic tumors. The results in these latter neoplasms

Fig. 145—Ventriculogram showing dilated lateral and third ventricles—supratentorial tumor.

occur on the side of the hemisphere involved. The gait may be typically 'cerebellar' with the toes turned out on the side of the lesion to prevent falling in that direction. Choked disks of long duration frequently with secondary optic atrophy are noted. A

are on the whole not as good since the tumors are frequently very large before they are detected and in the case of the acoustic tumor recurrence is much more frequent. The tumors are frequently cystic with simply a nubbin of astrocytoma in the lateral wall

The tumor originates in one or the other cerebellar hemisphere and does not as a rule involve the midline structures although because of its unilateral placement it often displaces the vermis to the opposite side.

The surgical approach is usually lateral since only occasionally can one be certain as to which side contains the tumor. In such cases the unilateral approach is preferable for acoustic tumors but with the latter in the bone carried to or slightly across the midline is entirely satisfactory. After the dura is opened a yellowish walled cyst may be discernible on the surface of the cerebellum. When the cyst is more deeply placed there may be no visible evidence of its presence. However the smaller surface vessels are usually collapsed giving a whitish or pale yellowish appearance and the surface markings are largely obliterated. By gentle palpation on an exploring cyst can frequently be detected. A ventricular needle can be passed into the cerebellum in various directions and the cyst located in that way. Frequently the location of the more solid portion of the tumor is detected by the resistance felt on the passage of the needle. If the cyst is superficial the cerebral vessels are lesioned and the cyst is opened.

After allowing the evacuation of yellowish serous fluid. When it is more deeply placed the overlying cortex is removed with the electric loop until the cyst is opened and the typical yellowish serous fluid is evacuated. The inner surface of the cyst wall is examined for the nubbins of astrocytoma which is practically always present. When the cyst is located its extent is determined and a wide excision made about the tumor. All vessels being either desiccated or divided between silver clips. The method of dealing with the tumor by which the latter is removed intact is preferable to piecemeal excision. However the latter is sometimes necessary especially when no cyst is present and the limits of the astrocytoma can not be readily determined. These tumors often extend to the midline but rarely involve the walls of the fourth ventricle or the vermis. The prognosis is excellent.

Cystic astrocytomas in the cerebrum are usually found in young adults. There is frequently a history of jacksonian epileptic attacks for several years. Headaches coming and visual disturbances are relatively late symptoms. The tumor may develop in any portion of the cerebrum but is found most frequently in the frontal and parietal regions. It is very slow growing and an enormous cyst is sometimes found in a patient presenting few symptoms.

The treatment is entirely surgical. An osteoplastic flap is reflected and the region of the tumor exposed. The cyst may extend to the surface of the cortex or may be more deeply situated. In the latter case it is located with an exploring needle and the yellowish fluid evacuated. The cyst is then

opened widely a transcortical or local incision being made when the lesion is deeply situated. A nubbin of relatively solid tumor is usually found arising in the cyst wall. This is completely excised preferably with the electric knife. The remainder of the cyst wall does not require excision as the nubbin usually constitutes the entire tumor. The prognosis is excellent although in those who have had epileptic attacks for years occasional attacks may be expected.

The infiltrating rapidly growing astrocytoma of the hemisphere carries a hopeless prognosis. This type is seen in children as well as young adults. Grossly the tumor tissue except for increased resistance cannot be differentiated from the normal white substance. It frequently infiltrates deeply into the basal ganglia and not rarely involves the opposite hemisphere. Complete surgical removal is impossible while x-ray treatment in no way retards the growth.

Microscopically the cystic types of astrocytoma show a feltwork of fibrillae with scattered nuclei and are composed almost entirely of fibrillary astrocytes. The infiltrating rapidly spreading astrocytoma is composed chiefly of protoplasmic astrocytes which show more evidence of growth. In Weigert sections the advance of the neoplastic cells with demyelination of the axon cylinders can be well seen.

Glioblastoma Multiforme.—This tumor was first described in 1924 by Gliosis and Strauss as spongioblastoma multiforme and is the most rapidly fatal of the glioma group. It usually involves the cerebral hemispheres in middle age. After the onset of the first symptom there is a rapidly progressive downhill course. Necrosis and minor hemorrhage frequently occur in and around the tumor giving rise to sudden paralytic striking a differential diagnosis from vascular disease difficult. Choked disk is sometimes absent adding to the difficulties of diagnosis. The symptoms are usually fulminating headache, mental changes and paralysis rapidly appearing.

The tumor is almost invariably subcortical and is usually located at operation by palpation which reveals an area of abnormal softening. When the overlying brain substance has been excised a vascular mass of varied appearance and consistencies is en-

countered Gelatinous as well as necrotic yellowish or grayish green areas are seen. A small ragged walled cyst may be present. The gross appearance is very characteristic. Microscopically various cellular forms are seen amid areas of necrosis. The predominant cell is small often spindle shaped with an oval nucleus. Mitotic figures are numerous. Multinucleated giant cells also are seen. All the embryological forms of glial cells are present. Many thin walled blood vessels occur.

Treatment—All forms of treatment of this type of tumor have proved futile. A large subtemporal decompression or actual re-

characteristic architecture. Blepharoplastin can be demonstrated within the individual cells.

The oligodendroglioma is a slow growing frequently calcified tumor with a predilection for the frontal lobes near the midline. Microscopically it presents a unique picture of round cells with spherical nuclei and abundant poorly staining cytoplasm.

The spongioblastoma polare is most commonly a tumor of childhood occurring within the brain stem, optic nerves and chiasm. Microscopically it is made up of unipolar and bipolar spongioblasts. The prognosis is hopeless when the tumor is located

Fig. 140.—Frontal glioblastoma multiforme showing ventricular distention. The ventricle is characteristically slightly dilated on the side opposite the tumor.

moval of the entire bone flap may give temporary relief. Complete excision of the tumor is impossible. The preferable procedure in these hopeless cases is the performance of so called internal decompression. In this operation a large amount of the tumor is removed and the skull and dura are closed tightly. Death may occur more quickly with the recurrence.

The ependymoma is a benign, often calcified intraventricular tumor with a predilection for the fourth ventricle. It is firmer and whiter than the other gliomas described. Microscopically it consists of ependymal cells definitely grouped in a radiating fashion around small blood vessels. This presents a

characteristic architecture. A tumor can be completely excised if it is located in one optic nerve. This of course necessitates excision of the optic nerve involved, usually with the adjacent portion of the chiasm.

The remaining rare tumors of the glioma group, the pinealoma, astroblastoma and neuroepithelioma, are too rare to be discussed here.

INTRAVENTRICULAR TUMORS

Intraventricular tumors present a very interesting group of brain lesions. They may occur in any portion of the lateral third or fourth ventricle. Several types have been found. The most common is the ependym-

oma, but fibromas, apparently identical in structure with the dural meningiomas, are not at all uncommon in the lateral ventricles and most frequently develop on the globe of the choroid plexus. Occasionally a tumor made up entirely of choroid plexus tissue is found. Several other types of tumors occasionally occur, perhaps the most interesting of which are the teratomas. One of the latter which was successfully removed from the third ventricle contained hair follicles and small intestine. Intraventricular tumors can be diagnosed only by ventriculography since the symptoms are largely those of simple intracranial pressure. Many

to be removed piecemeal which can be most readily done with the electric loop. At the completion of the operation the ventricle is filled with normal salt or Ringer's solution. No attempt is made to close the incision in the brain.

Tumors of the third ventricle offer more complicated problems. The osteoplastic flap must extend to the midline. An occipitoparietal flap is turned for tumors in the posterior part of the third ventricle and the dura incised making a flap with its base either forward or downward. The large veins, passing between the cortex and the superior longitudinal sinus, are doubly clipped and divided. The upper portion of the occipital pole is then gently dislocated outward exposing the posterior portion of the corpus callosum. This is incised in the midline and the incision carried through the tela choroidea and between the great veins of Galen into the third ventricle. Tumors in the an-

Fig. 147.—Ventricular displacement from cystic ependymoma. The cyst and ventricular system were injected with oxygen independently.

of these tumors are benign and accordingly every effort should be made to remove them completely.

The ordinary parietal osteoplastic flap, extended anteriorly or posteriorly depending on the location of the tumor, is the procedure carried out for a tumor of the lateral ventricle. After exposure of the cortex a nearly vertical incision is made in a relatively avascular area and either anterior or posterior to the Rolandic region. The cortical vessels are devascularized with the electric current, ligated with fine silk or caught with silver clips and the incision carried directly into the ventricle. The cut edges of the cortex are covered with sheet cotton. The ventricle is emptied of fluid by continuous suction and the walls of the incision are held apart with lighted retractors or brain spoons. Many ventricular tumors are pedunculated and it is only necessary to cauterize or clip the vessels in the pedicle and divide it to remove the tumor intact. Others have

tenor part of the third ventricle are approached through a frontal osteoplastic flap. The anterior part of the third ventricle may be opened by dividing the corpus callosum as in the posterior approach or the anterior lobe of the lateral ventricle may be exposed by resection of a portion of the frontal lobe. The third ventricle is then entered through the median inferior wall of the lateral ventricle. At times the growth thinned-out floor of the lateral ventricle about the obstructed foramen of Monro may be gently wiped away exposing the underlying tumor. Infiltrating lesions in the third ventricle cannot be successfully operated on and even in the relatively benign types the mortality is high, largely because of damage to the walls of the third ventricle and the resulting hyperthermia.

LITHIARY TUMORS

Three types of tumors of the pituitary gland are recognized. These are the *chromophil*, the *basophil* and the *chromophobe ad-*

enomas. Only the eosinophil and chromophobe adenomas are of surgical interest. The basophil tumor, because of its very small size, does not require surgical treatment and is best treated by deep roentgen therapy. The symptomatology of these three types of adenoma is distinctive, and except in a few cases in which a combined adenoma, characterized by hyperplasia of two of these cell types, occurs, the diagnosis can be made on the symptoms and physical findings alone.

The eosinophil adenoma produces gigantism if it develops before puberty. In an adult, it produces acromegaly, characterized by a marked overgrowth of the entire skeleton. This is most pronounced in the skull, hands and feet. Especially is there excessive development of the frontal sinuses, supra-

orbital ridges and lower jaw. The latter may be so enormously enlarged that the lower teeth project a half inch or more in front of the upper teeth. The hands and feet may become enormous. Severe headaches, usually of the hitemporal variety, are common, but visual disturbances are relatively late and may be entirely absent. Deep roentgen therapy has given excellent results in cases of acromegaly as far as relieving headaches and visual disturbances is concerned, but the skeletal changes rarely regress. Some patients are not influenced by x-rays, and surgical intervention is then indicated.

The basophilic adenomas are very small, frequently not more than 1 or 2 mm. in diameter, and are only found post mortem after careful section. They produce a very interesting group of symptoms now known as the Cushing basophil syndrome. This is characterized by rapid gain in weight, the adiposity being largely confined to the thorax and abdomen, hypertension, marked hirsutism, especially of the face, and the livid, coarse abdominal striae. Roentgenograms show a normal sella turcica, but marked depletion of calcium in the entire skeleton. The visual fields are normal. Deep roentgen therapy is the only treatment indicated.

Chromophobe Adenoma.—The chromo-

Fig. 148.—Rounded defect in third ventricle from teratoma of third ventricle.

The frontal operation previously described is the safest method of approach. The intranasal operation in which the floor of the sella turcica is removed, after

submucous resection has given excellent results but there seems to be a considerably higher mortality from meningitis, and for this reason it has been largely discarded. The frontal lobe is elevated gently exposing the right optic nerve and anterior portion of the sella turcica. The tumor is seen bulging upward between the optic nerves and in front of the chiasm. The latter may be pushed upward and backward and the optic nerves may be pushed laterally and upward. There is generally a thick capsule, and when it is opened a soft slightly granular adenoma is disclosed. This is gently removed with the curette. Bleeding points are desiccated with the electric current, and if there is considerably slow venous oozing, this can be readily controlled by pressing a small muscle graft into the sella turcica. It is not necessary or desirable to remove all of the adenoma. However, the upper part of the capsule must be freed from the optic nerves and excised. Otherwise, the vision may not be materially improved. The only indications for surgical treatment in chromophil adenomas is the continuation of headaches or visual impairment or both after deep roentgen therapy.

phobe adenomas constitute by far the largest group requiring surgical intervention. The function of the chromophobe cell is unknown. When the tumor develops before puberty there is usually failure in development of the gonads and of the secondary sexual characteristics, more or less marked obesity and in the extreme case the typical Frohlich syndrome of hypopituitarism called dystrophia adiposogenitalis. As a rule the chromophobe adenomas in children do not produce visual disturbances until the child is past puberty. When such changes are found in children a probable diagnosis of either pituitary adamantinoma or suprasellar cyst of Rathke's pouch origin can be made.

Symptoms—The symptoms of chromophobe adenoma in the adult are those of hypopituitarism. The earliest symptom is usually loss of libido in the male and diminution or cessation of menstruation in the female. As a rule all sexual functions are lost before the patient comes to the surgeon. The body hairs become scant and in men shaving is only necessary at long intervals or perhaps not at all. Headaches and visual disturbances may not appear for years after the sexual functions are lost. Very rarely some sexual ability and menstruation are maintained. There is usually more or less obesity and many patients have a subnormal basal metabolic rate. Headaches may appear at any time. At first these are bitemporal but after the tumor has penetrated the capsule and extended out of the sella turcica the headaches are more general. They may be exceedingly severe. The typical visual finding is usually considered a bitemporal hemianopsia but this occurs in only 50 per cent of cases. 25 per cent of the patients have either a right or a left homonymous hemianopsia and 25 per cent are so blind at the time of the first examination that the type of hemianopsia formerly present cannot be determined. Bitemporal hemianopsia results from stretching of the cross fibers in the chiasm. Homonymous hemianopsia may be due to pressure on one of the optic tracts posterior to the chiasm but is more commonly due to a notching of one of these tracts by the anterior communicating artery against which structure the tract has been firmly pressed by the underlying tumor. At times a deep groove may be cut across the optic tract and

even the chiasm by this firmly fixed artery. Other visual disturbances may arise from irregularities in the tumor which cause unequal pressure on various parts of the optic nerves or tracts. Marked impairment of vision may occur in one eye even total blindness with very little loss of vision in the other. This is generally the result of a sharp upward bending of the optic nerve at the optic foramen the superior rim of which may cut a deep groove. In the case of large tumors both optic nerve and the chiasm may be so stretched as to appear like thin white ribbons. Visual fields should be made with a small test object preferably not more than 1 or 2 mm in diameter. With such a test object very slight defects in the visual field may be detected and an early diagnosis made before the vision has been irreparably lost. The earliest finding is either a slight notching in the temporal field or a temporal skint. This latter term denotes a skinting defect usually occurring in the upper outer quadrant of the temporal field.

The treatment of a chromophobe adenoma is predominantly surgical. Deep roentgen therapy has been advocated by some workers but has been discarded in the majority of neurosurgical clinics. Practically all patients who have received that form of treatment eventually come to operation even those who had shown temporary improvement in vision. The primary object of the operation is to conserve the vision that is at present left. Loss of optic atrophy has developed much of the visual loss may be restored. The operation consists of turning an osteoplastic flap in the frontal region and approaching the sella turcica either intracranially or extracranially. The writer prefers the latter. The extracranial approach consists of elevating the dura backward to the sphenoidal table where a long incision in the dura is made extending to the malleus and the remainder of the operation is then carried out intracranially. The intracranial route consists in elevating the frontal lobe from its anterolateral aspect, carefully protecting the brain with sheet cotton as progress is made toward the sella turcica. Elevation of the brain is facilitated by tapping the lateral ventricle allowing escape of cerebrospinal fluid. The anterolateral approach is preferable to a direct anterior one. The right optic nerve is first exposed and then slight elevation medially will expose the left nerve protruding upward between the two will be seen the pituitary tumor. Occasionally the optic nerves are very short and the tumor presses upward back of the chiasm between the optic tracts. Some tumors grow irregularly upward and may appear more on one side of the midline. Occasionally they extend far out in the middle fossa and the capsule can be best incised lateral to the optic nerve. As a general rule the capsule is opened between the optic nerves. The vessels on the surface of the capsule are dissected and that portion of the capsule lying between

the optic nerves is excised. This makes subsequent procedures easier than through a simple incision.

The adenoma is generally soft and slightly yellowish, and there is frequently cyst formation. If the latter is diagnosed before the capsule is opened the cyst is aspirated. The contents are generally brownish or bile-stained frequently syrupy, and generally contain some yellowish crystals. A bluish capsule suggests a pituitary cyst. The more solid portions of the adenoma are removed with the curette or biting forceps. Complete eradication of the tumor should not be attempted. The upper portion of the capsule at least that part more or less adherent to the optic nerves and chiasm must be removed, and it is generally preferable to remove considerable of the lateral and posterior walls as well. Great care must be exercised in separating the lateral walls from the internal carotid arteries. The optic nerves and chiasm should drop down into normal position when the capsule is removed. At times the operation can be facilitated by dividing the anterior communicating artery. Continuous suction is of inestimable value in maintaining a dry field. Small vessels within the sella turcica may be caught with silver clips or desiccated with the electric current. A small muscle pack is useful in preventing slight oozing from the remaining pituitary tissue lying on the floor of the sella turcica.

Improvement in vision often appears rapidly. At times progress may be noted the first day. The degree of visual restoration depends largely on the duration of the visual loss. Marked optic atrophy is an indication of poor prognosis.

Pituitary adamantinomas occur almost entirely in children, but may be found at any age. The symptoms are those of hypopituitarism and differ in no way from those of the chromophobe adenomas. The diagnosis of an adamantinoma can generally be made from roentgenograms. These show deposits of calcium within the greatly enlarged sella and frequently calcium plaques extending well up into the brain. Calcification in other types of pituitary tumor is decidedly rare. The surgical procedure is identical with that for the chromophobe adenoma, with the exception that a serious attempt should be made to remove all of the tumor.

The suprasellar cysts which originate in Rathke's pouch present a rather common surgical problem in children. The symptomatology varies greatly. Some patients are unusually thin, suggesting the Lorain type of pituitary dystrophy, some are normal in physical development, and others are obese, with failure in development of the genitalia and secondary sexual characteristics. The cystic tumor may develop anywhere along the pituitary stalk. When the tumor arises at the upper end of the infundibulum, the

symptoms are largely those of increased intracranial pressure. The x-ray plate may show the calcified wall of a cyst lying in the region normally occupied by the anterior portion of the third ventricle. However, calcium deposits may not be demonstrable. The skull shows atrophy due to convolutional pressure, and the suture lines may be separated. The sella turcica and posterior clinoid process may be practically normal, but usually show evidence of pressure. Ophthalmic examination shows choking of the optic disks. The symptoms of the suprasellar cysts are predominantly those associated with interference with the circulation of the cerebrospinal fluid. A tumor developing in the lower part of the infundibulum may press directly on the optic tracts and chiasm, producing either bitemporal or homonymous hemianopsia. Depending on whether the tumor develops beneath or above the level of the chiasm, an early sign may consist of temporal defects in the upper or lower quadrant of the visual field. Primary optic atrophy is commonly found. Occasionally the tumor not only presses on the optic tracts and chiasm, but extends upward, elevating the floor of the third ventricle, and choking of the disks is superimposed on the primary optic atrophy. The sella turcica is generally enlarged and the posterior clinoid process destroyed comparatively early. The most characteristic roentgen finding is a crescentic calcified shadow, generally in the upper part of the wall of the cyst.

These suprasellar cysts may reach an enormous size, some have been found extending upward through the cerebrum nearly to the cortex and laterally to the surface of the posterior portion of the frontal lobe. Tumors of this size, while arising in the midline, are predominantly unilateral. The extent of such a cyst can usually be judged by the flecks of calcium shown in the x-ray plate; but if an exact determination is considered important, a small trephine opening can be made in the skull and a ventricular needle inserted into the cyst. After the contents have been aspirated, air or oxygen is injected and a roentgenogram made.

The surgical treatment for cysts of Rathke's pouch many of which contain adamantinomatous elements, varies with their location and size. The smaller cysts especially those within or just above the sella are ap-

proceeded as in the ordinary operation for a pituitary adenoma. Whenever possible all the cyst should be removed and occasionally it is even possible to remove the cyst intact. A large cyst is best approached by resection of the anterior portion of the frontal lobe, its section being carried backward until the complete cyst is well exposed. Even enormous cysts may be successfully removed by this procedure. The prognosis for life and vision is good provided the optic atrophy has not progressed to a serious extent and the floor of the third ventricle is not damaged during extirpation of the tumor. It is trauma to the walls of the third ventricle which produces the excessive hyperthermia feared by all surgeons when operating in this region.

MAN M. PEET

INJURIES OF THE SPINAL CORD

In spinal injuries it is not the dislocation, fracture or crush of one or more vertebrae that determines the severity of the symptoms. A very extensive vertebral injury can occur and if the spinal cord itself is not involved complete recovery follows. But frequently a crush of the cord accompanies apparently slight evidence of vertebral trauma. Severe and crippling loss of the motor and sensory function (even death) always results with little hope for useful recovery.

Injury to the spinal cord may result from direct external violence as from knife or gunshot wounds or the impact of heavy objects with dislocation or fracture of the spine, laminae, transverse processes or the body of one or more vertebrae. Concussion, compression, contusion or crushing of the cord substance or nerve roots with or without tearing of the meninges can occur. Any or all of these injuries to the vertebral column together with precisely similar effects on the spinal cord and meninges can result from indirect violence causing hyperextension or hyperflexion of the vertebral column.

Pathology.—Following vertebral injury a hemorrhage may be produced without or within the dura (hemitoraxus). Epidural hemorrhage comes from rupture of the veins in this region. The epidural fat and areolar tissue fill the epidural space so loosely that the hemorrhage can spread for several segments above and below the point of origin. Intradural subarachnoid bleeding results from the tearing of a vessel in the subarachnoid space about the cord. Many fine vessels float in the subarachnoid space accompan-

ing the spinal nerves or run to the dura lying posterior to the cord especially in the cervical region. Or the meninges may be torn at the time of injury, and blood may enter the subarachnoid space from the epidural spaces. Provided the cord is uninjured blood in the epidural or subarachnoid spaces does little harm. Occasionally adhesions may form about a clot which may later be a factor in the production of a circumscribed serous meningitis causing local cord compression. Lower motor neuron symptoms, pain and flaccid paralysis have been attributed to hemitoraxus but these complications must be due to an accompanying nerve injury. Following cranial trauma free blood in great quantities is often removed by spinal tap from the lumbar subarachnoid space. No evidence of anterior or posterior root irritation is produced by this stepping of blood downward from the intracranial cavity. It is highly improbable therefore that hemitoraxus alone in the absence of injury to the cord or roots produces symptoms.

Hematomyelia.—Damage to the cord itself results in varying degrees of contusion or laceration often sufficiently severe to cause complete section. As either one of these conditions results in hemorrhage into the cord the amount of hemorrhage being in direct proportion to the severity of the trauma it seems justifiable to group all cord injuries under the common heading of hematomyelia. The work of Allen³ and McVeigh⁴ has shown that hemorrhage and edema with destruction of fiber tracts are the outstanding results of any type of injury, either direct or indirect, to the spinal cord. The student is referred to McVeigh's⁴ work for a detailed account of the pathology in cord injuries.

Concussion of the Spinal Cord.—In concussion of the brain evidence is slowly accumulating to suggest that in spite of complete subsequent recovery there must be minute lesions to account for the sudden loss of consciousness. The occasional persistence of mild or severe headache following even slight concussion with only momentary unconsciousness confirms this opinion. Concussion of the spine falls into the same category. Following sudden severe jarring injuries there may be definite but fleeting evidence of a cord injury. Complete recovery suggests that what-

ever the lesion in the cord, it was of such a trivial nature that the term "concussion" of the cord seems justifiable.

Stages of Spinal Injury.—The progress of a spinal injury may be divided into three stages. (1) the stage of spinal shock; (2) the stage of reflex hyperexcitability, and (3) the terminal stage of diminished reflex ex-

may be noted, with a slight contraction of the inner hamstring muscles on scratching the sole of the foot. The reflexes slowly return. Within three or four weeks the stage of spinal shock gradually changes into that of reflex hyperexcitability. The reflexes become hyperactive. Stimulation of the sole of the foot produces a "mass reflex," with up-

Fig. 119.—The relation of the spinal segments to the vertebral column.*

citability, bladder infection, decubitus, etc. In the first stage complete loss of all motor, sensory and reflex action together with control of the sphincters is noted. The paralyzed limbs are flaccid. The extremities lie flat, partially rotated outward in semiflexion. Intestinal, bladder or rectal distention is not felt. In about ten days or two weeks these signs begin to disappear. A Babinski sign

ward movement of the great toes and a rapid contraction of the whole lower limb. Contraction in flexion occurs at the thigh and knee with extension of the ankle. The reflex expulsion of urine and feces may occur. Trophic changes in the skin with formation of decubiti take place. The third stage

*Homan's *J. Textbook of Surgery*, Charles C. Thomas, publisher

is simply a continuation of the second with a slow increase in the toxicity from exstisitis and ascending infection of the kidneys the spread of bed sores and wasting and atrophy of the paralyzed muscles until death occurs.

Symptomatology of Spinal Cord Lesions—Determination of the degree and extent of the injury to the spinal cord is based on the neurological findings. No matter what may have been the type of the injury regardless of evidence from local or roentgenologic examination of dislocation or fracture of the vertebral column if there is no demonstrable motor or sensory loss the spinal cord has not been damaged. The determination of injury to the spinal cord is easy and estimation of the level at which the cord has been injured is also easy but it is extremely difficult to be certain from the neurological findings whether complete and permanent destruction of fiber tracts has resulted or whether loss of function is due to local edema and pressure from which partial recovery at least may be expected.

Injury to the spinal cord exclusive of stab or gunshot wounds results from the impact of the indriven adjacent vertebra. Dislocation with immediate reduction can occur in the cervical region. Here particularly where extreme hyperflexion can occur it seems possible that overstretching of the cord without actual injury from displaced bone may result in a severe lesion. In the shift of position of the bones the cord is pinched and released. No roentgenographic evidence of displacement of bone is demonstrable but indications of a partial or complete cord lesion are all too obvious or the films may show dislocation or fracture with clear evidence of a narrowing of the bony canal and pressure on the cord. Whatever may be the manner in which the cord is injured there are always the two factors to be considered the complete destruction of fiber tracts and the physiologic block of other tracts from pressure consequent on edema and hemorrhage. A bullet or stab wound may cut the cord completely. Fracture or dislocation of the vertebra results in a crushing of more or less severity. Actual transection from the canal is rare. It is a good working rule that if after injury complete motor and sensory loss is present the cord has been hopelessly crushed. But if some degree of sensation and move-

ment remains part of the loss of function may be due to hemorrhage and edema in the cord substance. When this edema subsides and the hemorrhage is absorbed considerable return of function may occur.

Treatment of Cord Injury—Following injury these patients are all in shock and any immediate treatment must be directed to its relief. Great care must be taken in handling or transport lest the injury to the bone be increased with further cord damage. The patient should be carried prone on a stiff well padded litter. If a stretcher is used boards should be placed across the handles for the usual canvas trough permits too much sagging. Pain from pressure on nerve roots may be relieved by opiates although it must be remembered that in cervical cord injuries respiration may be already impaired by phrenic involvement hence morphine must be used cautiously.

While the history of the accident is important in furnishing an idea of the severity of the injury whether hyperflexion or hyperextension has occurred and to what degree or whether or not there are accompanying injuries that might account for any of the symptoms of still greater importance is an attempt to discover what power the patient had in his limbs when he first attempted to move them and how much subjective loss of sensation seemed present. Usually there will be no difference in the patient's condition immediately after injury and at the time the first clinical examination is made. But there will be an occasional case in which evidence of progressive loss or improvement in neurological signs can be demonstrated soon after injury. This fact is of such value in determining the subsequent treatment that every effort should be made to learn this information.

When the patient reaches the hospital he should be placed on a well inflated air mattress or if this is not available on a stiff hair mattress supported by boards across the bed frame and not by a sagging spring. A soft pillow beneath the lumbar curve of the spine will increase the patient's comfort. Regarding any external evidence of injury to the vertebral column either dislocation or fracture as bruises muscle spasm local pain and tenderness kyphosis absence of normally palpable pulsations processes or alteration in

the vertebral curves or position of the head attention should be directed to determining the extent of sensory and motor loss.

Since sensory loss to touch pain and temperature will give more exact evidence of the level and extent of the injury to the cord than motor involvement this examination should be carefully and methodically undertaken. In complete lesions there will be an abrupt and segmental line of anesthesia to all forms of sensation. Very frequently just above the point at which sensation is lost a band of hyperesthesia will be noted. Often a level of increased vasomotor activity as shown by slight flushing or blanching of the skin or marked dermatographism will be observed in the dermatomes supplied by the spinal nerves running from the injured cord segments. Priapism will often be seen and increased sweating will frequently be noted its distribution depending on the level of the lesion. Sympathetic fibers arising from the second thoracic to the second lumbar segments innervate the sweat glands. If the lesion lies above the second thoracic segment profuse sweating may occur in all parts of the body. But if the cord is injured below this level the perspiring area may lie below the level of the sensory loss.

In describing sensory or motor loss following cord injury the level of anesthesia and paralysis in various muscle groups resulting from injury at the different cord segments is best outlined from below upward. The lower the trauma in the cord the less is the sensory and motor loss. Hence it is less confusing first to describe the result of a sacral lesion for any anesthesia or paralysis accompanying a low complete lesion will also be present in a similar injury at a higher level.

A lesion in the lower sacral segments results in a narrow strip of anesthesia on the back of the calf and thigh merging above into an area of perineal and scrotal anesthesia. Flexion but not extension of the foot and toes is lost and sphincter control is much impaired. If the fifth lumbar segment is spared when the upper sacral segments are damaged sensation is abolished over the dorsum of the toes and the plantar surface of the foot plus a narrow strip up the back of the legs and thighs and the perineal region. Flexion and extension of the feet and

toes is impossible and control of both sphincters is lost. Injury at the fifth lumbar level results in impaired movement at the knee with paralysis of the toes ankles and sphincters. The knee jerk is unimpaired the ankle jerk lost. The sensory loss will involve the outer side of the leg from the knee downward the whole of the foot and the perineal and scrotal regions. Following trauma at the fourth lumbar segment sensation will be absent below the knees and loss of power in flexion and extension of the thighs together with impairment of the knee jerks will be added to the neurological findings already described. In lesions below the third lumbar segment not only may the lower end of the cord be involved but since so many pairs of nerve roots from higher segments pass down across this area they may become implicated thus producing a motor and sensory loss suggesting a lesion above its actual position. Furthermore since below this region both roots and cord may be injured asymmetrical and partial lesions are frequently encountered. Injury to the cord at the second and third lumbar segments produces a sensory level corresponding roughly to the middle of the thigh. Knee and ankle jerks are lost but the cremasteric reflex is retained. Complete flaccid paralysis is noted in the legs and sphincters. Lesions in the thoracic area are best localized by the sensory level. In all descriptions of lesions to be outlined next complete paralysis of the legs and sphincters must be considered as included. The sensory loss accompanying lesions at the twelfth thoracic segment corresponds roughly to Poupart's ligament at the tenth thoracic to a line through the level of the umbilicus at the sixth thoracic to the level of the ensiform cartilage at the third thoracic to the line of the nipples and at the first and second thoracic to the line of the clavicles and the inner side of the upper arms as well.

In the motor sphere complete loss of contraction of the abdominal muscles together with abolition of the abdominal reflex indicates a lesion above the eighth thoracic segment. The upper extremities are not involved until the injury reaches the first thoracic segment. With a lesion of the seventh cervical segment the patient lies with his forearms flexed and crossed on his chest. The biceps

reflex may be preserved but the triceps jerk is lost together with contraction of the triceps. The forearm can be flexed but not extended. Slight movement of the wrist and fingers may be present. Sensation is preserved on the outer side of the forearm and hand. In a lesion of the eighth cervical and first thoracic segments contraction of the pupils and narrowing of the palpebral fissure with enophthalmos are produced by sympathetic involvement. If the sixth cervical segment is injured the upper arm can be abducted and externally rotated and the forearm flexed and pronated; is partial motor power is retained in the shoulder girdle. The biceps reflex will be impaired or lost. No movement in the wrist or fingers will be possible. Sensation may be preserved in the outer side of the upper arm. With a lesion of the fourth cervical segment or above motion in both arms will be completely lost. The diaphragm will be paralyzed with consequent danger of pneumonia due to phrenic involvement. Sensation is absent below the base of the neck.

In all these lesions at various levels it has been presumed that the destruction of the cord has been complete. While this is unfortunately only too often the case in many instances the lesion is not complete and hence variations in motor and sensory findings can occur. Since from the standpoint of prognosis and treatment differentiation of a partial from a complete lesion is of extreme importance a review of the clinical findings in either instance seems indicated. In a full transverse lesion of the cord paralysis of the flaccid type is complete in all muscles innervated by segments below the level of the lesion. Reflexes are completely abolished below the level. Sphincter control of the bladder and rectum is gone. Complete retention is noted and later urine and feces pass without the knowledge or volition of the patient. There is an entire loss of all forms of sensation sharply confined to the level of the involved segments and usually capped by a band of hyperesthesia. The clinical picture is stationary.

However when the lesion of the cord is not complete the paralysis of muscles below the injured segment may not be absolute and the paralysis is rather of the spastic than the flaccid type. The reflexes below the level

of the lesion may be present or even increased. A Babinski sign or clonus may be obtained. Partial control of sphincteric action may remain, and the patient may appreciate that his bladder or rectum is overdistended and when evacuation occurs. Sensory loss is not complete and may not correspond to the level of the injured segment. Strong stimuli and changes in position of the paralyzed limbs may be felt. Lastly the clinical evidence may change rapidly or slowly with a return of power in the muscle groups and diminution in the area of anesthesia.

After a careful neurological examination and detailed recording of the findings roentgenographic studies of the area of the vertebral column involved must be made. Great care must be taken in moving the patient lest cord damage be increased. Every effort should be directed in this examination toward a determination of the amount of impingement of the bone on the neural canal and hence possible direct pressure on the cord. Anterolateral and anteroposterior films are always indicated. Based on the roentgen findings it is often possible to reach a conclusion as to the probable degree of injury to the cord. It will be at once obvious in many instances that the cause of a complete lesion has been the crushing of the cord by the vertebral dislocation. A finding of this character will have an important bearing on subsequent treatment. Frequently roentgen studies will show that the vertebral injury involves a somewhat lower segment of the cord than the level indicated by the neurological findings. This apparent discrepancy may be explained by the fact that at the time of cord injury pulped cord has been driven upward along the fiber tracts within the spinal sheath and has destroyed higher areas or hemorrhage may have spread upward within the cord substance. Further more in the lumbar region where the nerve roots run from above downward their involvement at a lower level may suggest that the higher segment from which they originate has been damaged.

A lumbar puncture should always be made to determine first the presence or absence of blood in the spinal fluid and secondly and more important the presence or absence of a block in the spinal fluid circulation at the level of the lesion following

compression of the jugular veins (Queckenstedt test) If the spinal fluid is clear the lesion is not due to an effusion of blood into the subarachnoid spaces (hemitorachis) If no evidence of a block is present it is obvious that there is no impingement of the overlying bone on the lumen of the neural canal nor is the cord swollen from edema or hemorrhage consequent to trauma But if signs of a block can be found then either the fractured or dislocated vertebrae are compressing the cord or edema and hemorrhage consequent on the injury have caused a local swelling of the cord Or a combination of both bony compression and local swelling may cause the obstruction A study of the roentgen films should furnish evidence of the degree of vertebral impingement on the neural canal If there is no dislocation or fracture the block is due entirely to local post traumatic hemorrhage and edema in the cord

Based on the results of these examinations an attempt may be made to decide whether or not the cord has been completely or incompletely injured and whether the symptoms are due to pressure from the overlying bone or to edema and hemorrhage into the cord resulting from the trauma or both

The purpose of all treatment in cord injury is to obtain the maximum return of function in the groups of paralyzed muscles lying below the lesion The injury of the cord may be due to continued pressure from adjacent bone to hemorrhage into and pulsing of the cord at the point of impact to edema of the cord from the bruise or to a combination of all three of these factors Pressure against the cord from a dislocated or fragmented vertebra can frequently be shown by roentgenographic studies The time element is very important in deciding on the type of treatment Unless the existing pressure on the cord is relieved within eight hours the damage will be permanent Therefore unless the patient is seen within that period little or nothing need be done as far as relief of pressure is concerned

What are the methods by which pressure may be relieved? Two methods are available closed reduction of the fracture or dislocation or laminectomy over the level of the lesion The neurological examination will reveal a complete or partial lesion with

stationary increasing or diminishing symptoms The roentgen ray studies may show whether or not the neural canal has been narrowed by the impingement of the surrounding bone Lumbar puncture and the Queckenstedt test will prove whether a complete partial or no block exists

It is the author's belief that no complete cord lesion should be operated on regardless of whether the roentgen ray studies show a narrowing of the neural canal or whether a complete block can be shown by the Queckenstedt test In these cases laminectomy is a waste of time and causes the patient suffering from a useless operation Laminectomy is indicated only when the neurological signs are progressive block or no block and whether or not there is roentgenographic evidence of bone pressure It is true that the author has operated in cases in which there was pressure from damaged vertebrae and has found an edematous swollen cord has removed the bone opened the dura and relieved the tension A certain amount of recovery resulted But one is not convinced that an equal amount of recovery might not have occurred without operation In many cases if the cord has not been entirely crushed even though evidence of a complete lesion may be present at the first examination a surprising amount of function is recovered spontaneously Great pressure may be brought to bear on the surgeon He may feel that if the lesion is complete and if the Queckenstedt test is positive a decompressive laminectomy may give the patient a slight chance for a little increased improvement in function Such is not the fact

The author has operated on seven patients with cervical injury and has seen eight operated on by others without recovery The one patient with a cord injury in this region who recovered to the author's knowledge did so without operation

The opinions here expressed as to the treatment of acute spinal injuries are not universally held Mixer⁶ states that patients showing increasing neurological signs or stationary neurological signs plus complete block demand immediate laminectomy if seen within twenty four or forty eight hours of injury Mock⁷ Naffziger⁸ Coleman⁹ Semmes¹⁰ and Gurdjian¹¹ all subscribe to this opinion Elsberg¹² adds severe root pains

from pressure of the located bones on one or more sensory roots as an indication for operation.

If following injury to the vertebral body with involvement of the cord roentgen ray studies show fracture or dislocation manipulative reduction of the deformity by hyperextension is indicated. (See section on *Fracture of the Spine*.)

Cervical fracture and dislocation with cord injury is always serious.

With regard to the late treatment of spinal injuries and by late is meant from two weeks onward after the initial trauma there seems to be general agreement. Operation is indicated if there are increasing clinical signs of cord damage. If the condition is stationary regardless of whether or not a block exists no improvement is to be expected from surgical measures. Manipulative reduction should be attempted in these cases as well unless the interval of time has been too great.

After Care of Spinal Injury.—The decision for or against operation and the performance of a decompressive laminectomy or closed reduction in a spinal cord injury is only the opening gun of a long struggle. Vesical retention must be relieved, the development of trophic changes in the skin with the formation of bedsores must be prevented and contractures in paralyzed muscles must be combated.

The proper handling of urinary retention is a much discussed problem. Mixer⁹ weighs against the use of the catheter. He and Cahill¹⁴ suggest suprapubic pressure on the fundus of the bladder in an attempt to cause relaxation of the sphincter and the escape of urine. This deep pressure should be made every second hour expressing about 2 ounces at first and increasing the amount up to 6 or 8 ounces at the end of ten days. If this fails then Mixer introduces a large de Pezzer catheter into the bladder through a suprapubic stab wound. With Gurdjian¹⁵ the writer has found that an in lying catheter released every six hours to prevent overdistention and changed every three days gives the best results. Repeated catheterization leads more surely to infection than an in lying catheter. Bladder irrigations with mild solutions are indicated after each catheterization.

Bed-sores following spinal cord injury are very difficult to prevent. Elimination of pressure points by the use of an air or water bed is essential. The heels should be protected by gauze rings. Frequent turning if this is safe will help prevent the breakdown of the skin over the buttocks and trochanter. The skin must be kept absolutely dry. Alcohol rubs followed by stearate of zinc powder should be given every four hours to the back. One of the great objections to suprapubic drainage or manual expression of urine for vesical retention is that with these methods of handling the bladder condition it is difficult to keep the buttocks dry. If and when bedsores appear every effort should be made to prevent infection although this is impossible. If sloughs occur they should be allowed to separate and should not be cut away. Deep collections of pus should of course be evacuated.

Muscle contractures, toe drop or flexion at the knee are best combated by the use of light splints. If a cast is applied every precaution must be taken to prevent a pressure sore.

TREATMENT OF MENINGITIS

No more dramatic step in the conquest of a dreaded complication of sinus infection cranial trauma or operative procedures in the brain has been taken than that resulting from the discovery that the sulfonamide derivatives had a specific action against the common organisms producing meningitis. The treatment of meningitis has been radically changed by the introduction of these drugs. Surgical measures which were at best desperate makeshifts have been forced into the background. They should be used only as aids to sulfonamide therapy to clean up a feeding focus of infection to relieve pressure or to unblock cerebrospinal fluid circulation obstructed by the adhesions consequent upon meningitis. Certain organisms are not definitely affected by these compounds and in such cases laminectomy and drainage may be necessary adjuncts to these drugs. But the treatment of meningitis due to streptococci pneumococci staphylococci or meningococci infection consists in prompt diagnosis by lumbar puncture smear or culture and the immediate administration of the proper sulfonamide preparation in full dosage. If possible the patient's condition permitting it as soon as the proper blood level of the drug is reached the original source of infection—maxillary or paranasal sinus compound fracture or septic focus elsewhere—should be drained and sterilized at the earliest opportunity to prevent reinfection.

The dosage of these drugs by mouth is as follows

	Initial Dose	Maintenance Dose	Interval Day and Night
Adults—100 lbs or over	30-50 grains	15-20 grains	Every 4 hours
Adults—50 to 100 lb	30-30 grains	10-15 grains	Every 4 hours
Children	20-30 grains	5-10 grains	Every 4 hours
Babies	10-20 grains	5 grains	Every 4 hours

The maintenance dose should be continued until the temperature has been normal for seven days. The higher dosages are recommended for sulfanilamide by mouth in handling streptococci and meningococci meningitis; the smaller amounts for sulfapyridine orally in staphylococci meningitis and for sulfathiazole orally in pneumococci meningitis.

If the patient is too sick to take the drug by mouth or nasal tube intravenous therapy is indicated. For staphylococci meningitis sodium sulfapyridine should be given in an initial dose of 0.06 gm per kilogram of body weight made up in a 5 per cent solution in sterile freshly distilled water. It is important to give

this solution slowly and carefully by vein avoiding the passage of the material into the surrounding tissue where it may cause a slough. Never add the sodium sulfapyridine solution to other material given intravenously such as blood glucose or normal saline solution. Subsequent doses should be calculated on the basis of 0.03 gm per kilogram of body weight and given intravenously every six hours. As soon as the patient's condition warrants it sulfapyridine should be given by mouth.

In the treatment of streptococci meningitis the patient may be given sulfanilamide intravenously if he is too sick for adequate oral administration. Add 80 gm of sulfanilamide crystals to a liter of freshly prepared normal saline solution which has been brought to a boil. One hundred cubic centimeters of this solution contains 120 grains of sulfanilamide. This solution may be given under the skin. The initial dose is 20 grains for an adult followed by a maintenance dose of 40 grains every four hours day and night. (Follow the tables on oral administration.)

Pneumococci meningitis may be treated by intravenous therapy with a 5 per cent solution of sodium sulfathiazole in sterile distilled water in an initial dose calculated at 0.06 gm per kilogram of body weight. Subsequent doses intravenously every six hours should be given calculated at 0.03 gm per kilogram of body weight. Hemologous type antipneumococci serum intravenously is recommended in pneumococci meningitis in late cases or if response to chemotherapy is not prompt and adequate. If the patient is not hypertensive to serum an initial dose of 500,000 units is advisable with a supporting dose of 100,000 units every eight hours.

During the use of any of these drugs a record of urinary output should be kept and the excretion should never be permitted to fall below 1000 cc in twenty-four hours. If this rule is strictly observed complications referable to the urinary tract from the use of these drugs will be avoided. Fluid should always be forced up in at least 2500 cc per day especially when sulfathiazole is being administered and the output of urine should be kept at 1000 cc daily as a minimum. None of these drugs should be administered by lumbar puncture or ventricular tap. Repeated lumbar taps or continuous lumbar drainage is not advisable.

As therapy spinal puncture may be done when indicated to determine the bacterial and cellular content of the spinal fluid. In treating all forms of meningitis it is advisable to have the blood level of the drug reach 15 mg per hundred cubic centimeters as soon as possible and to maintain it at or near that level until clinical improvement is clearly obvious. Since the blood level drops rapidly it is important to maintain the level by repeated doses every four hours orally or every six hours intravenously day and night.

The drug treatment of pneumococci or staphylococci meningitis is greatly aided by the judicious use of surgical measures. Feeding focus should always be elim-

nated whenever the condition of the patient permits. Since these organisms produce tick pus with a lichenous and interference with the circulation of cerebrospinal fluid surgical treatment may be indicated to relieve block or intracranial pressure.

It is to be recommended that when possible laboratory control of bacterial chemotherapies be carried out but inability to do examinations of the blood and urine should never be considered a contraindication to the use of the sulfanilamide compounds. If facilities are available hemoglobin determinations should be made every other day during the first week of treatment and once a week thereafter. Total and differential white blood cell counts should be made every other day for the first seven days and (particularly important) if the patient continues treatment with sulfanilamide or its derivatives every two days between the fourteenth and the fortieth day. The urine should be examined on alternate days if the patient is receiving a sulfapyridine or sulfathiazole. The urine should be examined microscopically for blood. The output of urine of patients being treated with sulfathiazole or sulfapyridine for serious infections should be recorded daily. Patients receiving sulfanilamide compounds should be seen at least once a day and should be questioned as to the presence of headache or malaise, as these are frequently important early symptoms of toxic reactions. Patients should be inspected at each visit for the presence of jaundiced sclerae (acute hemolytic anemia or hepatitis), pale mucous membranes (acute hemolytic anemia) or rash. The temperature should be recorded. If fever recurs after the patient's temperature has been normal in the course of treatment with sulfanilamide or one of its derivatives the drug should be discontinued immediately or if recently discontinued should not be resumed unless it has been demonstrated that the fever is due to a recurrence of the infection. Whenever therapy with the sulfanilamide drugs is stopped because of a drug reaction fluids should be forced so that 5000 cc per day is taken in order to wash out the drug.

Agranulocytosis is extremely rare before the fourteenth day of therapy. It is imperative that total and differential white cell counts be made for patients still under treatment after the fourteenth day (every two days from the fourteenth to the fortieth day). If the percentage of polymorphonuclear leukocytes falls to 50 per cent or less in an adult patient the drug should be stopped immediately. Granulocytopenia without agranulocytosis may occur.

Any patient who has had a toxic reaction to one of the sulfanilamide group of drugs may have a second and more severe reaction if one of these drugs is prescribed again. In such patients a small test dose of the drug (0.1 to 0.3 gm) should be given and the patient observed twelve hours before a therapeutic dose is started following which he must be carefully observed and the drug immediately stopped on the first appearance of any toxic manifestation.

TUMORS OF THE SPINAL CORD

Because of the clinical importance of their relation to the cord and its covering membranes spinal cord tumors have been divided into three major groups: (1) *intramedullary tumors* arising within the substance of the cord or medulla; (2) *extramedullary tumors arising outside the cord* and (3) *tumors of the cauda equina* arising within the dura and among the nerve roots of the cauda equina. The extramedullary tumors are subdivided into *intradural* and *extradural* according to their relation to the dura (Fig. 150).

Signs and Symptoms.—The early signs of spinal cord tumors are determined largely by the position of the neoplasm in relation to the cord and to the emerging nerve roots. A tumor arising from a nerve root may give symptoms referable to the nerve root long before there is any evidence to suggest spinal cord involvement unless this latter possibility is definitely considered in the differential diagnosis. If on the other hand the tumor compresses the spinal cord in its early stages the signs readily suggest the true site of the pathologic process. Accordingly neoplasms of the spinal cord may be considered as presenting two groups of symptoms: (1) those due primarily to compression of the nerve roots and (2) those due to early compression of the long fiber tracts of the spinal cord.

With compression of the long fiber tracts the signs are the obvious ones of disturbed spinal cord function and the attention is at once directed to the cord. The problem is then to determine whether the clinical picture is attributable to a tumor to some intrinsic disease of the cord such as multiple sclerosis or to a systemic disease such as pernicious anemia. The earliest clinical manifestations of which may be referable to spinal cord involvement before evidence of the condition is demonstrable in the blood picture.

When on the other hand the early signs are due to involvement of the nerve roots within the vertebral canal without obvious compression of the cord these are referred to the peripheral distribution of the involved roots. The symptoms may then be confused with symptoms referable to disturbed functions of such organs as the kidney, gallbladder, appendix or prostate and

become sufficiently great, abolition of the sensory impulses

Paresthesias, such as tingling, pins and needles sensation and finally a sense of heaviness or dead feeling, referred usually to the side of the lesion, arise from pressure on the dorsal columns. Pressure on the spinothalamic tracts more commonly causes a sense of burning or of extreme cold and, finally, loss of the pain and temperature sense referred to the opposite side of the body. Thus, a tumor on the left side of the spinal cord causing pressure on the dorsal columns will produce a sensation of pins and needles in the left lower extremity and, if

tension (Babinski), and, in long-standing cases with marked compression of the cord, massive withdrawal reflexes, the extremities being withdrawn involuntarily on the slightest stimulation, such as moving the bed covers or merely touching the skin in testing sensation. At first only a sense of heaviness and slowing of movement without active loss of movement may be noticed, gradually increasing until marked spasticity and loss of voluntary movement occur.

Involvement of the short, but multiple neuron pathway controlling bladder and rectal function is evidenced by disturbances in urination, difficulty in starting the urinary

Fig 151—Photomicrograph of a transverse section of the cervical cord of a five week old infant, Weigert myelin stain

the tumors is sufficiently ventral to cause pressure on the left spinothalamic tracts, a sense of burning or of icy cold in the right lower extremity.

The long motor pathway, known as the pyramidal system and controlling voluntary movement, is the only clinically important motor system, since signs arising from involvement of this tract overshadow those due to the less prominent motor systems, such as the rubrospinal.

The principal signs referable to compression of the motor pathway are motor weakness, spasticity, increased deep reflexes, diminished abdominal reflexes, altered plantar responses, that is, fanning or dorsal ex-

flow, urgency or, if certain segments of the cord are involved, incontinence. Unless the cord segments directly controlling the bladder and rectum are involved, signs referable to the bladder occur relatively late in the course of extramedullary spinal cord tumors, frequently not until the motor signs are massive and the sensory changes are advanced. In intramedullary tumors and in intrinsic diseases of the cord, such as multiple sclerosis, they appear early.

Root or Radicular Syndrome—Unilateral root involvement may occur in tumors arising directly from the nerve roots within the subarachnoid space, or the root may be compressed secondarily by tumors arising from

the search may lead away from the spinal cord instead of to it, sometimes even to the point of surgical exploration of the suspected area. For this reason, even though few signs of cord involvement are present, symptoms referable to a given organ but failing to fit the clinical picture usually presented by that organ should arouse suspicion of a spinal cord tumor.

For convenience, the signs of extramedullary spinal cord neoplasms may be grouped

sure may be exerted on the roots for many years with only vague signs to suggest the presence of the tumors.

Long Tract Syndrome.—So far as the clinical signs of spinal cord tumors are concerned, the function of only the two major long neuron pathways need be considered. These are the sensory and motor paths. While a number of other tracts are recognized and their function is well known, their involvement is, as a rule, overshadowed by

Fig. 150—Schematic drawing to show the relation of tumors to the spinal cord and dura

in two syndromes: the long tract syndrome and the root or radicular syndrome, either of which or both may be present. Intra-medullary tumors involve primarily the central gray matter of the cord, and the symptoms from the so-called central gray syndrome. In effect the clinical picture is a combination of the bilateral radicular syndrome and the syndrome of the long tracts. Tumors of the cauda equina are usually large, soft, jelly-like masses surrounding the nerve roots and producing radicular signs. Because of their jelly-like consistency pres-

sure may be exerted on the roots for many years with only vague signs to suggest the presence of the tumors.

The important *sensory tracts* are: (1) the dorsal sensory columns of Goll and Burdach, which carry discriminative sensation, such as muscle, joint and tendon sense and vibratory and discriminative tactile sensation from the same side of the body, and (2) the lateral and ventral spinothalamic tracts, which carry pain and temperature from the opposite side of the body (Fig. 151). Pressure on these afferent pathways produces first, paresthesias and, finally, when it has

become sufficiently great, abolition of the sensory impulses.

Paresthesias, such as tingling, pins and needles sensation and finally a sense of heaviness or dead feeling, referred usually to the side of the lesion, arise from pressure on the dorsal columns. Pressure on the spinothalamic tracts more commonly causes a sense of burning or of extreme cold and, finally, loss of the pain and temperature sense referred to the opposite side of the body. Thus, a tumor on the left side of the spinal cord causing pressure on the dorsal columns will produce a sensation of pins and needles in the left lower extremity and, if

tension (Babinski), and, in long-standing cases with marked compression of the cord, massive withdrawal reflexes, the extremities being withdrawn involuntarily on the slightest stimulation, such as moving the bed covers or merely touching the skin in testing sensation. At first only a sense of heaviness and slowing of movement without active loss of movement may be noticed, gradually increasing until marked spasticity and loss of voluntary movement occur.

Involvement of the short, but multiple neuron pathway controlling bladder and rectal function is evidenced by disturbances in urination; difficulty in starting the urinary

Fig. 131—Photomicrograph of a transverse section of the cervical cord of a five week old infant, Weigert myelin stain

the tumors is sufficiently ventral to cause pressure on the left spinothalamic tracts, a sense of burning or of icy cold in the right lower extremity.

The long motor pathway, known as the pyramidal system and controlling voluntary movement, is the only clinically important motor system, since signs arising from involvement of this tract overshadow those due to the less prominent motor systems, such as the rubrospinal.

The principal signs referable to compression of the motor pathway are motor weakness, spasticity, increased deep reflexes, diminished abdominal reflexes, altered plantar responses, that is, fanning or dorsal ex-

flow, urgency or, if certain segments of the cord are involved, incontinence. Unless the cord segments directly controlling the bladder and rectum are involved, signs referable to the bladder occur relatively late in the course of extramedullary spinal cord tumors, frequently not until the motor signs are massive and the sensory changes are advanced. In intramedullary tumors and in intrinsic diseases of the cord, such as multiple sclerosis, they appear early.

Root or Radicular Syndrome.—Unilateral root involvement may occur in tumors arising directly from the nerve roots within the subarachnoid space, or the root may be compressed secondarily by tumors arising from

the meninges at the point of emergence of the nerve root or by tumors lying outside the dura adjacent to the foramen of exit of the nerve as it leaves the vertebral canal.

Pressure on the nerve may give rise to pain referred to its peripheral distribution. Thus involvement of the eighth cervical root may give rise to pain in the hand of the fourth thoracic root to pain in the breast and of the seventh or eighth thoracic root on the right side to pain in the region of the gallbladder.

A tumor on a nerve root may exist for a long time without producing definite sensory changes referable to the root involved or if

spinal cord from within and expand so as to cause pressure on the neural components of the cord at the point at which the neoplasm takes its origin. The more central portion of the spinal cord consists of the gray matter through which the crossing pain and temperature fibers pass and the ventral gray horns from which the motor roots emerge. The signs arising from a tumor in the substance of the spinal cord are due therefore to the segmental involvement of the crossing pain and temperature fibers and of the ventral nerve roots and to compression of the long fiber tracts as well. The clinical picture is a combination of the radicular and long

Fig. 15.—Schematic drawing to show the relation of tumors to the spinal cord and the nerve roots of the long fiber tracts. A Radicular syndrome. B central gray syndrome. C long tract syndrome.

the tumor arises from the ventral motor root before it has joined the sensory root the earliest signs may be atrophy of the muscles supplied by the root fibrillary twitches and weakness. Frequently however the tumor involves both the sensory and the motor root and both sensory and motor functions are disturbed simultaneously with atrophy appearing in the region in which pain is felt. Thus the symptoms and signs are due at first to the nerve root alone. Later signs of cord compression and involvement of the long pathways are added to the clinical picture (Fig. 15^o).

Central Gray Syndrome.—Intramedullary tumors in their early stages involve the

fiber tract syndromes partly segmental and partly suprasegmental.

In their earliest stages intramedullary tumors present the syndrome of root involvement since they usually early implicate the ventral gray motor cells and some of the incoming sensory fibers. This involvement however is usually bilateral that is implicating the ventral roots of both sides in contrast to the unilateral involvement in extramedullary tumors. In addition intramedullary tumors early interfere with the crossing pain and temperature fibers as they pass through the central gray matter while other forms of sensation are affected only later. Thus in the early stages of an intra-

medullary tumor, one sees disorientation of sensation with bilateral segmental loss of the pain and temperature sense and bilateral motor weakness and atrophy. By dissociation is meant loss of the pain and temperature sense without loss of tactile or discriminative sensibility. The number of body segments in which this loss is found depends on the longitudinal extent of the tumor.

In general it may be said that in intramedullary tumors the sensory loss is greater in the body segments nearest the involved segments of the cord while in extramedullary tumors the greatest loss is in the more peripheral segments that is those farther away from the level of the tumor (compare sensory charts Fig 163).

Owing to involvement of the central gray matter and the fibers that immediately surround it disturbance of the bladder and rectal functions occurs earlier in intramedullary than in extramedullary tumors.

Because of their symptoms intramedullary tumors have frequently been mistaken for chronic poliomyelitis or syringomyelia or some other form of intrinsic disease of the spinal cord.

Diagnosis—If the physician's attention is early focussed on the spinal cord as the probable seat of disease the nature of the pathologic process can usually be determined by a combination of the history, the neurological signs and the special tests.

Frequently even the expert is unable to distinguish by neurological signs alone between spinal cord tumors and atypical forms of multiple sclerosis, syringomyelia, atrophy of the cord or combined sclerosis, all of which may give rise to signs of long tract and radicular involvement. In such cases a detailed history in which the exact chronological sequence of signs and symptoms is elicited is essential. Frequently by the history alone the level of the tumor and its relation to the spinal cord can be determined. Thus if the first symptom is pain referred to the right side of the chest in the nipple line, if this is followed by numbness and tingling in the right leg with weakness in the right leg and a sense of extreme cold in the opposite leg if on getting into his bath the patient does not feel hot water on the left leg as well as on the right and if the history shows a gradual and progressive ex-

clusion of symptoms with evident signs of spinal cord involvement it is fair to assume the presence of an extramedullary tumor involving the right fourth thoracic root compressing the spinal cord laterally on the right side so as to involve the right pyramidal tract, the right dorsal column and the right spinothalamic tract.

Most chronic intrinsic diseases of the spinal cord do not materially increase the size of the cord; in fact some of the chronic degenerative diseases cause it to atrophy. A neoplasm on the other hand either increases the size of the cord or fills the vertebral canal within whose rigid walls it is en-

Fig. 163—Chart showing typical sensory changes for (1) extramedullary and (2) intramedullary tumors. Note that the greatest sensory loss in intramedullary tumors is in the proximal segments.

closed. Thus spinal cord tumors are expanding lesions which form an obstruction like a dam across the narrow vertebral canal, obliterating the subarachnoid space, preventing the flow of the spinal fluid and compressing the cord, whereas the intrinsic diseases cause no obstruction of the subarachnoid space, no block of the spinal fluid and no compression of the cord itself.

Among the lesions producing subarachnoid block are spinal cord tumors, inflammations, both acute and chronic, displacements of the vertebrae or intervertebral disks and hypertrophic arthritis. Among the spinal cord tumors may be listed the following:

Intradural

Ghoma
Ependyoma
Medulloepithelioma
Hemangioma

Extramedullary-Intradural

Meningioma
Perineural fibroma
Neurofibroma (von Reckh-
hausen)
Fibrosarcoma
Lipoma
Hemangioma

Extradural

Chondroma
Sarcoma
Lymphosarcoma
Fibrosarcoma
Chordoma
Osteoma
Fibroma
Hemangioma
Myeloma
Simple cyst

The evolution of symptoms in such widely divergent pathologic entities must of necessity show great variation. Important determining factors, in addition to the position of

a tumor which is soft and extremely vascular may be subject to intermittent alterations in size dependent on changes in the local blood supply and consequently may

Fig 154—Spinal manometric chart showing a delayed rise in the presence of an extramedullary meningioma attached to the dura. Part of the tumor was soft and part had formed dense bone. Note the delayed rise shown in the accompanying manometric chart. Unless the manometric readings were carefully made, the total rise might be considered normal, whereas, the delayed rise is definitely indicative of an obstructed subdural space.

the tumor, which has been discussed, are its consistency and rate of growth. It is obvious that compression by a hard tumor will cause greater damage than would be produced by a soft tumor of the same size. Furthermore,

display intermittent variations in its symptomatology. Even in tumors of the same type, such as meningiomas, great variation in consistency may be found. Some are very soft, while others have the hardness of bone.

Obviously the evolution of symptoms in these two instances will be dissimilar even though the tumor in each case is a meningioma.

causes an increase in the subarachnoid spinal fluid pressure as measured by a lumbar puncture needle and a water manometer when the space is obstructed by a tumor or

Fig. 153—Schematic drawing showing relation of an extramedullary tumor to the spinal cord after removal of the fluid barrier.

The rate of growth will also determine the progress of the symptoms. Where a structure is confined within rigid walls as is the spinal cord symptoms appear earlier with the more rapid growth of the tumor.

normal rise does not occur. Unfortunately the significance of this phenomenon described many years ago by Queckenstedt was not fully appreciated until relatively recently when it was submitted to intensive

Fig. 156—Enlargement of the cervical vertebrae and the vertebral canal due to the presence of an intracanal lipoma.

Manometric Test—In making a differential diagnosis between tumors and intrinsic spinal cord diseases special tests such as the manometric study of the spinal fluid are of great value. Compression of the veins of the neck in an unobstructed subarachnoid space

study and a number of important modifications of the test were introduced. The routine manometric study of the spinal fluid has become one of the most important procedures in the study of spinal cord diseases.

* *Arch. Neurol. & Psychiatry*, vol. 18.

The test however if it is to be of value must be carefully performed and the essential details observed the period of compression being timed and the rise and fall in the manometer noted accurately every five seconds. Done in a haphazard manner without due attention to details the procedure is of little value. A lumbar puncture should never

to 40 mg of protein per 100 cc and is clear in the presence of a tumor the amount of protein is increased frequently to 100 or 200 mg and in long standing cases to 1000 mg or more so that coagulation of the fluid occurs.

*Determination of the Tumor Level—(1) Sensory Level—*By careful observation of

Fig 157

Fig 158

Fig 159

Fig 157—Multiple neurofibromas. Showing tumors lying ventral to the nerve roots and on one side extending through the vertebral foramen forming a dumb-bell tumor (von Recklinghausen).

Fig 159—Large meningioma compressing the spinal cord, conus and cauda equina.

be made in these cases without measuring the spinal fluid pressure with a water manometer.

*Examination of Spinal Fluid—*Compression of the spinal cord by tumors causes pressure on the blood vessels diapedesis an increase in the protein content of the spinal fluid and if long standing xanthochromia. Normally the spinal fluid contains from 20

the level at which lost or diminished sensation becomes normal the sensory segmental level of a tumor is determined. When the tumor involves a nerve root a zone of hyperesthesia may at first be found and this may give way to a zone of loss of sensation below which sensation may be present but diminished. If the sensory level is not definite it may be accentuated by deliberate

removal of from 10 to 15 cc of spinal fluid. The cerebrospinal fluid acts as a buffer to support an extramedullary tumor and the latter on removal of the fluid will press directly on the cord making possible the demonstration of a definite sensory level (Fig 155). Any increase in symptoms after removal of spinal fluid is generally a welcomed sign, since it suggests the presence of an extramedullary rather than an intramedullary tumor. Removal of fluid is without effect on intramedullary tumors, since it causes no change in their position. (2) *Motor Level*—Focal atrophy, fibrillary twitchings and focal paralysis are significant evidence of the segments of the cord involved except in such muscles as the intercostal where they are not readily observed.

X-ray Changes Indicative of the Tumor Level—Enlargement of the spinal canal by pressure atrophy of the vertebrae may be demonstrable in x-ray plates and may indicate the exact position and extent of the tumor (Fig 156). Not infrequently certain extradural tumors such as osteomas, chondromas and some meningiomas, may be seen directly in the roentgenogram.

In a comparatively few instances when neither a sensory nor a motor level can be determined otherwise, iodized poppy seed oil may be injected into the cistern and the level of the obstruction determined roentgenographically.

Segmental and Vertebral Level—Since the spinal cord is shorter than the spinal canal the segments of the former do not correspond to the overlying vertebrae except perhaps in the cervical region. In the upper thoracic region each spinal segment lies approximately two vertebrae higher than the corresponding vertebra and in the lower thoracic, three higher.

Indications for Treatment—Once the diagnosis of a spinal cord tumor is established, the tumor should be removed. When this cannot be done, as in the case of certain intramedullary tumors a wide decompression is indicated, i. e., removal of the vertebral arches and opening of the dura.

Types of Operation—Two types of operation for tumors of the cord are available: (1) bilateral laminectomy, in which the spinous processes and laminae on both sides are removed and (2) hemilaminectomy

(Alfred S. Taylor), in which the spinous processes, interspinous ligament and laminae on one side are left intact the laminae of only one side being removed. This second type of operation is more difficult and requires greater skill than the first, but properly performed is preferable in the cervical and lumbar regions especially if the bones have been eroded by the neoplasm or if the tumor is ventral to the spinal cord. For exploratory purposes in these two regions it is also the best procedure. A hemilaminectomy can be converted with little difficulty into a bilateral laminectomy should conditions demand it.

No more brilliant results can be found in surgery than those following successful removal of a spinal cord tumor and fortunately the majority of these tumors are removable. Symptoms are relieved, the bedridden patient walks again and the paralyzed and helpless resumes, in many cases his former life of activity.

INJURIES OF THE PERIPHERAL NERVES

Etiology.—Injuries of the peripheral nerves may occur as the result of direct injury by gunshot or stab wounds. They may occur in dislocations of joints and in fractures, resulting either from the immediate injury or later from compression of a callus. Injuries are produced by pressure of casts or bandages, prolonged pressure in sleep, anesthesia or wasting disease, compression by new growths, osteoarthritis of the spine, traumatic aneurysms, cervical ribs, prolonged stretching in some occupation or an unusual position during an operation, excessive use of muscles as in long thoracic nerve palsy, and continued mild trauma, as in peroneal palsy in cyclists. Nerves may be injured at birth, by spinal anesthesia, by accidental intraneural injections, in the neuritides produced by toxic substances and infectious disease and by contagious inflammatory processes.

Pathology.—When a nerve has been severed or severely injured the distal segment undergoes wallerian degeneration, the neurofibrillae become swollen, fragmented and granular and disappear. The myelin is broken up into masses and globules and vanishes. Soon after injury regenerative changes, with an increase in the amount of granular cytoplasm, occur in both segments, but such abortive fibers as are formed in the distal segment degenerate in from three to eight days. In the proximal segment, after an increase in cytoplasm, the nuclei increase and by the fourth to sixth day protoplasmic bands are formed, affording pathways along which the regenerating neurofibrillae from the proximal segment find their way, as well as into empty sheaths in the distal segments. True regeneration occurs only from the proximal segment.

When a nerve has been severed, the ends separate. Immediately the formation of scar tissue begins between the severed ends. When the regenerating axons of the proximal segment reach the end, they are unable to penetrate the connective tissue and are turned back in a twisting spiral coiling mass which goes to form the proximal bulb or true neuroma. The end of the distal segment becomes enlarged into a bulb by for-

mation of connective tissue and forms the distal bulb or false neuroma.

When a nerve is incompletely severed, a lateral notch with a subsequent lateral notch neuroma is formed. A nerve injured only internally may give rise to a fusiform neuroma.

When a nerve is injured by compression by a callus or scar tissue following extensive injury to some adjacent structure, it may be displaced and surrounded by a scar which may be diffuse or band like. The nerve itself, smooth or rough, usually is gray and firm and may contain an increase of connective tissue and new nerve fibers.

Symptomatology.—When a peripheral nerve is severed, a motor paralysis, a loss of touch, temperature, pain and deep sensibility in the area supplied by this nerve, a loss of vasomotor supply and so called trophic changes ensue.

When a nerve is but partially injured, the loss of function is incomplete, and if only a part of a nerve is completely severed or severely injured, then only some of the muscles will be paralyzed and a part of its sensory supply will be anesthetic.

The paralysis, affecting the lower motor neuron, is a flaccid one, associated with atrophy and a "reaction of degeneration" to electrical stimulation.

Muscles which produce certain movements may be supplied by more than one nerve. Because of this and other mechanical reasons a movement expected to be impossible because of a particular nerve palsy may be performed by other unaffected muscles, this is known as supplementary motility, an example is extension of the wrist in radial nerve palsy by strong closure of the fingers.

When a nerve is severed there is loss of sensation to touch, temperature and pain in the cutaneous sensory supply of that nerve. Such an area is fairly constant in distribution and extent for each particular nerve. Joint and vibration or deep senses are also lost, but over a much smaller area the reason for which is explained in the next paragraph.

Sometime after severe injury to a particular nerve it will be found that there has been a return of sensation to more severe pin prick and high or low degrees of tem-

perature (protopathic sensation) on the borders of sensory loss. This early return of certain sensations must not be interpreted as a sign of regeneration or of incomplete lesions. It occurs as the result of assumption of function of adjacent injured nerves and is known as a sensory overlap. It occurs in areas peculiar to each individual nerve. For example, it never occurs in the distal phalanges in lesions of the ulnar or median nerve. Overlap may be so extensive in the radial nerve that the loss of pain to severe pin prick may completely disappear but the loss of tactile sense will always be found.

After the initial trauma pain is rare in complete interruption of a nerve. In partial lesions, with the exception of cases in which causalgia develops, paresthesia, hyperesthesia and pain are not as frequent or as severe as one might expect. In the areas where sensation to pain returns as the result of overlap, a peculiar sensitivity to stimuli occurs, described as a hyperpathic reaction.

In certain partial lesions a severe at times unbearable pain occurs precipitated by contact with dry surfaces, jolting, even emotional changes. At times it is relieved by keeping the skin moist and because of continued moisture the skin is macerated. Under normal conditions it is often glossy and smooth so that such cases have been described as glossy skin and causalgia.

As a consequence of an injury to a peripheral nerve the affected muscles atrophy, but the amount of atrophy is no indication of the severity of the injury. Marked early and extensive atrophy is typical in lesions of the ulnar nerve that sometimes are not severe.

Flaccidity is characteristic of peripheral nerve lesions. But a short time after injury it is often masked by fibrosis of muscles and fibrosis, ankylosis and capsular shortening of joints.

Many so-called trophic, vasomotor and secretory changes are seen following peripheral nerve injuries: keratosis, ulcerations, atrophy of the skin and failure of desquamation, increased and diminished sweating, overgrowth and ridging of nails, overgrowth of hair and atrophy of muscle. Ulcerations of the skin initiated by some form of trauma occur in an analgesic area, as the distal seg-

ment of the little finger in ulnar nerve lesions or the proximal phalanx of the index finger in a median nerve palsy.

About ten to fourteen days after a nerve is severed or severely injured a change occurs in its irritability to electrical stimuli and likewise in the muscles it supplies. The nerve loses its irritability and the muscle no longer responds to the faradic current. During the state of complete denervation, when the reaction of degeneration is complete, the muscle is hyperirritable to galvanic stimuli. When recovery begins the amount of current necessary to produce contraction suddenly increases. During the state of denervation the anodal closing stimulus becomes as effective as the cathodal closing one. The contractions of the muscle are slow and vermicular like and tetanus throughout the flow of current results from stimuli little stronger than those which produce liminal contraction. With progressive currents of long duration over a second during denervation the amperage is very low for all time. During regeneration there is a sudden marked rise of amperage for increasing durations. The muscle likewise requires a stimulus of much longer duration whatever its strength so that during denervation the chronaxie is increased. Strength-duration curves show a discontinuity during regeneration.

Other causes of inability to move a part or the whole of an extremity must be differentiated from an injury to a nerve. For example, section of tendons or muscles. Here the muscle proximal to the injury will contract when stimulated by electricity, but no movement will be produced in the segments about a joint which it normally moves.

Diagnosis.—When it is determined that a nerve is injured it is imperative to know whether it is partially or completely interrupted, whether by severance or compression. When only some of the muscles supplied by a particular nerve are completely paralyzed and sensation particularly to touch is preserved within the limit of the sensory supply of the nerve and the reaction of degeneration does not develop in the muscle after fourteen days the nerve is only partially injured and operative treatment should be deferred. Whether a nerve is severed or severely compressed, all function

may be lost so that at a particular time all the muscles may be completely paralyzed and a complete sensory loss may be present and the reaction of degeneration may have developed. Only if at a later date there is observed a return of some of the functions can one say that the nerve is not severed.

If it has been determined that a nerve has been injured it becomes necessary to discover the particular nerve involved. A comprehensive knowledge of anatomy and physiology is necessary for accurate diagnosis

aspect of the radial side of the hand and thumb and part of the proximal phalanges of the index and middle fingers. Because of the extensive overlap there may be very little or even no loss of pain to severe pin prick.

When the *median nerve* is severed the thumb is held in the plane of the palm producing a simian or ape hand. Because of supplementary motility many movements expected to be impossible may be present. The most characteristic defects are inability

Fig. 160—*a* Wrist drop in paralysis of the radial nerve. *b* clawing of inner two fingers in paralysis of the ulnar nerve. *c* inability to oppose all fingertips in paralysis of the ulnar nerve. *d* the left compared with the normal right hand. *e* inability to make a fist in paralysis of the median nerve. *e* trophic ulcers in paralysis of the median nerve. *f* inability to oppose the thumb to the little finger in paralysis of the median nerve.

Some of the pronounced signs of nerves most commonly injured will be described.

When the *radial nerve* is injured a position of wrist drop is seen. Often a dorsal protrusion of the metacarpal bones is seen. The patient is unable to extend the wrist, the proximal phalanges of the fingers and the thumb, and to abduct the thumb in the plane of the palm. If the lesion is high enough the brachioradialis is paralyzed and if still higher he cannot extend the forearm because of paralysis of the triceps. There is a loss of sensation over the dorsal

to oppose the thumb to the little finger forming the letter 'o' because of paralysis of the opponens pollicis when an attempt to make a fist is made the index finger remains partly or completely extended because of paralysis of the flexor indicis and flexor profundus digitorum. The distal phalanx of the thumb remains extended because of paralysis of the flexor longus pollicis. The same position can be brought about by trying to interlock the fingers by clasping as in prayer. When an attempt is made to approximate all of the fingertips only the

little ring and middle fingers succeed. Abduction of the thumb at right angles to the plane of the palm is impossible because of paralysis of the abductor. Sensation is lost over the radial side of the palm, the lateral surface of the index finger, the middle finger and the radial side of the ring finger. At times sensation may be conserved in the ring and the ulnar side of the middle finger. On the dorsum of the hand there is a loss of sensation in the distal two phalanges of corresponding fingers. Because of extensive overlap pain to deep pin prick may return except over the distal phalanges of the index and middle fingers.

The position assumed by the hand in ulnar nerve palsy is that of a *clawing* of the ring and middle fingers because of overaction of the extensors.

What is true of motor disability because of supplementary movements in the median nerve is also true in the *ulnar nerve*. Among the characteristic disturbances is an inability to grasp a flat object between the thumb and index finger except by ineffective action of the flexor of the thumb because of paralysis of the adductor pollicis. There is an inability to move the middle finger laterally, the other parts of the hand being immobilized, also to approximate the tips of the little ring and middle fingers and to abduct the little finger effectively. Sensation is lost over the little and the ulnar side of the ring fingers and corresponding part of the palm, the distal two phalanges of the little and the ulnar half of the ring fingers and corresponding part of the dorsum of the hand. Because of overlap pain to deep pin prick may return in all parts except the distal phalanges of the little finger.

When both the *ulnar and median nerves* are severed a similar type position of the hand results. No flexor movements of the wrist or fingers are possible and movements of the little finger are lost, the thumb can only be abducted in the plane of the palm and extended. The sensory loss is the combined ulnar and median distribution and overlap occurs only on the radial side of the palm, index and middle fingers.

Although lesions of the *brachial plexus* are divided into upper or lower and inner, outer or posterior cord lesions, often there are lesions of the whole plexus, part of which

recovers leaving a residue which is then classified. In an upper brachial plexus or Erb's palsy, often seen as birth palsy, the fifth and sixth roots are involved and produce a paralysis of the deltoid, biceps and brachioradialis muscles. In lower brachial plexus lesions, also often in birth palsy, there is a paralysis as of a combined ulnar median nerve palsy, as is the case in a lesion of the inner cord. In lesions of the posterior cord there is a paralysis of the deltoid, the muscles supplied by the radial and subscapular nerves. In a lesion of the outer cord there is a paralysis of the biceps, brachialis anticus, supplied by the musculocutaneous, and the muscles supplied by the median nerve exclusive of the intrinsic muscles of the hand.

When the *sciatic nerve* is severed there is a paralysis of all the muscles below the knee. Because the fibers to the biceps femoris, semimembranosus and semitendinosus are given off high in the thigh they are often spared. There is a loss of sensation over the outer side of the leg and the whole foot except the inner surface proximal to the sole.

When the *peroneal nerve* is severed the foot hangs in a plantar flexed position, known as *foot drop*. The patient is unable to flex or extend the toes or the foot or to evert the foot. Inversion is possible by feeble action of the tibialis posterior supplied by the tibial nerve. The sensory loss extends over the outer side of the leg, a strip over the dorsum of the foot from the inner two or two and a half toes to a line in the middle of the outer surface of the great toe and the great and adjacent toe. Because of overlap at times a very narrow strip over the dorsum of the foot is the only area completely anesthetic to all sensation.

Operative Treatment—In a partially injured nerve when indications of continued regeneration cease or in one whose function is completely interrupted but where other evidence indicates compression rather than anatomical section, operative treatment is indicated when after a period of time (three to six months) no evidence of recovery is seen. Some operations formerly described and performed in complete section as nerve flaps, nerve implantation, tubular sutures and suture a distance have been found to be futile. An end to end suture is the best

method of repair and when impossible nerve transplants and nerve crossing are the methods of choice

When a nerve is sutured immediately or very soon after injury the operation is referred to as a primary suture. As the results of early repair are far better than those of other procedures it should be attempted in almost all instances. It is certainly indicated when a nerve is accidentally cut in operation or torn by stretching fracture or dislocation. It should also be performed in injuries sustained by gunshot wounds or stabs when no suppuration of the adjacent structures is present. Many advise it in such cases as well. Although suppuration will often interfere with regeneration no harm has been done by the suture and retraction of the nerve ends will have been prevented facilitating a subsequent secondary suture.

When primary suture is performed the injured lacerated or contused ends of the nerve should be resected until healthy funiculi are exposed. Usually these will be found a short distance from the point of injury but at times a considerable part of the nerve end must be resected. The ends of the nerve must be united as anatomically perfectly as possible that is without torsion by epineurial sutures which by some are combined with two transfixion sutures. The suture material of choice is a strand of the finest Corticelli black silk although some advise fine (000) chrome catgut. The ends should be brought together without compression and all tension avoided the epineurium must be accurately closed absolute hemostasis is necessary and greatest delicacy is indicated in the handling of the nerve so as to avoid injury. When sutured the nerve should be allowed to repose in its former bed if no trauma or scar tissue is present but if the latter condition exists a new bed should be found in the plane between uninjured adjacent muscles.

In secondary sutures the injured nerve ends on which bulbs have been formed will be found embedded in scar tissue which must be resected. To expose the nerve ends it is advisable to begin the dissection some distance from the scar or site of injury. The position of the two parts of the nerve should be identified by fine silk sutures so that axial rotation may be avoided. When it is found

that no traction on the nerve is necessary to unite the ends the bulbs should be resected with the finest and sharpest knife (for example a safety razor blade) until healthy funiculi bulge out. The ends are then approximated as in a primary suture. When because of extensive injury or retraction the ends are too far separated to permit of suture they may be approximated by flexion or extension of the extremity the ends brought as closely together as possible by fairly heavy sutures and the extremity gradually returned to its normal position thus stretching the nerve. If this procedure is successful the ends may then be sutured. If a large defect is present recourse may be made to mobilization or dissection of the nerve out of its bed for some distance beyond the point of injury. By this means at times without change of position of the extremity (flexion or extension as the case may be) the nerve ends may be approximated. At times it may be possible merely by the change of position of the extremity to approximate the ends of the nerve. Then the extremity is immobilized in that position for six weeks. Often it is possible to approximate the severed ends of the nerve by displacing the course of the mobilized nerve for example displacing the ulnar nerve at the elbow from the groove behind its inner condyle anteriorly.

The suture line as in primary suture must be protected from scar tissue by placing it in a bed in the plane between healthy muscles. If this is impossible at times Cargile membrane may be used to surround the suture. When none of these procedures suffices to permit an end to end suture nerve transplantation may be performed. In this operation a cutaneous nerve such as the superficial branch of the radial the external cutaneous nerve of the thigh etc. is removed and divided into several pieces forming a cable which is interposed between the severed ends of the injured nerve and sutured to them. When regeneration does not occur in the distal end of such a repaired nerve a resection and suture of this end may later become necessary because of the formation of scar tissue.

Irremediable defects in nerves may be treated by tendon and muscle transplantation or arthrodesis of joints. At times good

results have been described by direct implantation of a severed end of a nerve into a muscle (direct neurotization).

When a nerve has only been compressed by scar tissue or a bony callus the severed nerve may be dissected free from scar tissue and placed in a new bed. This procedure is known as neurolysis. The operation is indicated in those cases in which the lesion is chiefly extraneural and is most successful when the nerve is compressed by a constricting band. At times when the scar tissue around the nerve has been removed the nerve is found to be indurated. In such cases the sheath of the nerve must be incised (internal neurolysis). Some of the funiculi may be found to be severed and a suture of part of the nerve may be necessary, at times because of the extent of the injury resection and suture may be indicated.

Following an injury to a nerve before operation is performed and following the operation until recovery has occurred over stretching of the paralyzed muscles and overaction of unopposed muscles leading to deformities must be prevented by proper splinting. The extremities should be splinted to place the muscle at rest usually midway between its extremes of movement in either direction. Physiotherapy directed toward prevention of fibrosis capsular contraction of joints fibrosis and atrophy of muscles should be used before and after operation. This should consist of heat massage passive movement electrical stimulation of paralyzed muscles and later re-educational exercises.

LEWIS J. POLLOCK

TUMORS OF THE PERIPHERAL NERVES

Tumors of the peripheral nerves become important clinically and surgically whenever they produce pain dysfunction or increasing tumefaction. These tumors may arise in the nerves themselves or in other tissues of the body that contain nerves or nerve filaments. In order to study tumors that occur on the extracranial and extravertebral nerves Stout, Laulaw and Haagensen suggested a classification that has been modified to permit a surgical consideration of the subject.

TUMORS OF THE PERIPHERAL NERVES

- 1 True neuromas traumatic neuroma
- 2 Tumors involving nerve terminals neurovascular glomus tumor, pigmented mole
- 3 The specific nerve sheath tumor peripheral fibrosarcoma of Penfield neurinoma sometimes erroneously called a neurofibroma
- 4 The nerve sheath manifestations of von Recklinghausen's disease terminal neurofibroma sheath neurofibroma plexiform neurofibroma fibroma molluscum
- 5 Questionable tumors lipoma hemangioma Pringle's disease or adenoma sebaceum
- 6 Malignant tumors fibrosarcoma neuroepithelioma, metastatic tumors

TRUE NEUROMAS OR TRAUMATIC NEUROMAS

A tumor of this type consists of proliferation of the axis cylinder the sheath of Schwann and the fibroblastic tissue and appears on the proximal end of a divided nerve or a severely traumatized nerve in which normal repair has been prevented. The clinical history usually reveals that trauma has been followed either by pain or by loss of function. Palpation will reveal some tumefaction. The treatment is surgical and an attempt should be made to remove the neuroma and anastomose the normal nerve (Fig. 169 a and c).

TUMORS INVOLVING NERVE TERMINALS

Glomus tumors or tumors of the neurovascular glomus are the result of hypertrophy of organs found beneath the nails in the cornua of other parts of the hands and feet and in other parts of the upper and lower extremities. The tumor usually appears as a bluish or purplish subcutaneous or subungual nodule although no discoloration or projection may be detectable. A patient suffering from a glomus tumor usually seeks relief from severe pain which centers around a small area in one of the extremities. The pain is in the arm leg foot or hand the lesion occasionally is situated beneath the finger nail or toenail and the patient complains of exquisite pain which occurs at intervals or when pressure is made on the nail. The glomus is a complex of small arteries and veins composed of a sinuous vessel lined with

endothelium. Masson and Popoff expressed the opinion that these vessels control arterio-venous circulation and body temperature. An encapsulated tumor forms in the glomus frequently affecting young and emotionally unstable women. The striking clinical characteristic is pain which occurs in paroxysms and which may attain an agonizing intensity. The pain may come on spontaneously or may be initiated by trauma, pressure, changes in temperature or other causes. Although such tumors usually occur singly, two instances of multiple tumors are on record. The treatment is surgical; simple excision of the tumor is followed by immediate relief of symptoms.

Pigmented moles are tumors that usually are not considered with tumors of the peripheral nerves. The distinctive features of a pigmented mole are the presence of nevus cells in the dermis and the intimate connection between these nevus cells and the sensory nerves of the skin. These features indicate that the pigmented mole is a step in the evolution of sensory nerve terminals in human skin.

THE SPECIFIC NERVE SHEATH TUMOR (PERIPHERAL FIBROBLASTOMA OF PENFIELD, NEURINOMA, SOMETIMES ERRONEOUSLY CALLED NEUROFIBROMA)

This group of tumors comprises the single isolated tumors of the peripheral nerves which are similar in structure to the intraspinal and intracranial tumors of the nerve. Peripherally, a tumor of this type involves not only a large nerve but also many small branches. Of the large nerves which are affected the median, ulnar, sciatic and radial nerves are involved in this order of frequency. The tumor is often palpable beneath the skin and may attain considerable size without causing pain, paresthesia and paresthesia. It is always attached to a nerve in which it may be embedded. The nerve fibers, however, do not enter the body of the tumor as they do in a true neurofibroma but pass around it. The tumor as a rule is benign and encapsulated. It does not metastasize although it may recur locally unless removed completely. The growth is usually slow and although malignant change has been reported in these tumors, such a change

is more frequent in true neurofibromas. It is the consensus that such a tumor develops from the sheath of the nerve, is fibrous and has a highly specific morphologic structure which is reminiscent of tumors of the endoneurium or sheath of Schwann. It causes symptoms of pain and interference with function and often becomes soft, serous or cystic. The growth of the tumor is generally slow, periods of quiescence alternating with periods in which its size increases rapidly. The treatment is always surgical (Fig. 163) and as the tumor is encapsulated it is possible in almost every instance to excise it successfully and at the same time to spare the nerve trunk if it is of importance. It is rather safe to assume that malignant changes do not occur in this type of tumor. Microscopically, the most typical feature of this tumor is the arrangement of nuclei in zones, palisades or whorls.

THE NERVE SHEATH MANIFESTATIONS OF VON RECKLINGHAUSEN'S DISEASE

Neurofibromatosis or von Recklinghausen's disease is a hereditary systemic disease which involves the nerves primarily. It is characterized by single or multiple tumors on the nerves by pigmentation of the skin by *café au lait patches* (Fig. 161) and sometimes by endocrine disorders. Neurofibromas are usually palpable beneath the skin and are often painful. They may be very numerous; they may follow the course of a single nerve trunk or may be scattered.

The characteristic feature of von Recklinghausen's disease is a proliferation of the tissues composing a peripheral nerve including both the axis cylinder and its sheath. This overgrowth may take place along the course of the nerve and may produce encapsulated tumors called neurofibromas or it may produce general thickening, elongation and tortuosity of the nerve. The latter changes comprise a plexiform neurofibroma. The overgrowth may also occur about the peripheral terminations of a nerve; it may produce non-encapsulated nodules in the skin called cutaneous neurofibromas or it may cause a generalized thickening of some superficial area called elephantiasis neuro-matosa.

These tumors are encapsulated in a

smooth white fibrous covering on cross section the nerve fibers even macroscopically may be seen to enter and leave the tumor. If degeneration has taken place in the tumor its contents are likely to be gelatinous but if degeneration has not taken place the cut surface is smooth dense and shiny and on close inspection is finely granular. Microscopically the outstanding characteristic of a neurofibroma is the presence of nerve fibers which pass through the tumor. The tissue is seen to be rather loosely arranged and to contain long curving oat-shaped nuclei and bundles of collagen fibers. There may be portions in which the histologic picture resembles that of perineural fibroblastoma.

Neurofibromas may occur in any situation, they are benign and grow slowly. At times they may be painless and symptomless for many years or they may give rise to local pain and to paresthesias as a result of their size.

Heredity is an important factor as evidenced by studies conducted by Preiser and Davenport on 30 families. In 47 per cent of the cases in which one parent was affected all the children showed some signs of the disease such as pigmentation or multiple tumors. Trauma may be an exciting factor as the tumors appear at the site of a bruise or along the line where clothing has exerted pressure on the skin.

The prevalence of malignant change in these tumors was pointed out by Garré who found that it occurred in about 10 per cent of cases in his series. Courvoisier found 53 instances of sarcomatous change in 500 cases of neurofibroma of the malignant tumors 15 were pure sarcomas and the remainder were myxosarcomas and fibrosarcomas. In the majority of cases in which tumors that have been removed are found to have undergone malignant change the tumors tend to recur locally or regionally within a year. Clinically it is difficult to distinguish between simple neurofibromas and perineural fibroblastomas on the one hand and those in which malignant change has occurred on the other hand because within the same tumor regions of malignancy may be adjacent to simple neurofibromatous tissue. For this reason every tumor of a peripheral nerve should be examined microscopically

and when a slowly growing neurofibroma that produces but few symptoms increases rapidly in size and is associated with increased paresthesia hyperesthesia or motor changes malignant degeneration should be suspected.

The treatment of multiple neurofibromas or von Recklinghausen's disease depends a great deal on the clinical manifestation of the tumors. It would be impossible in some cases to remove surgically all the tumors

Fig. 161.—C café-au-lait spots with A neurofibroma producing a bulging resistant mass in anterior aspect of left iliac

that are present (Fig. 161). However any of the tumors that produce pain, tumor, function, paresthesia or paresis should be removed surgically and the patient should be instructed not to worry about any of the other tumors unless there is a sudden increase in size or some clinical manifestation.

TUMORS WITH A QUESTIONABLE RELATION TO NERVES

Multiple or single hemangiomas, lipomas, fibromas, fibromyxomas, fibrosarcomas and

neuroblastomas as well as sebaceous adenomas (Pringle's disease), may be associated with other indications of von Recklinghausen's disease and their relation to tumors of the peripheral nerves is questionable.

MALIGNANT TUMORS

Malignant tumors of peripheral nerves are not common; they are of the mesoblastic type and are more inclined to occur in von Recklinghausen's disease or in connection

lungs and pleurae are most commonly affected; the diaphragm, liver, bones and neck are rare sites of metastatic involvement.

The treatment of malignant tumors of the peripheral nerves is surgical, although the local attempt to eradicate them may fail. Radical operation seems to be the treatment of choice. These tumors are radioresistant; however, radiotherapy should be used and if all types of treatment fail, amputation should be resorted to.

Fig. 102.—Surgical treatment of tumors of peripheral nerves. Diagrams representing resection and excision of tumors and anastomosis of nerves.

with the neurofibromas than with the peripheral fibroblastoma of Penfield. In a small number of cases of neurofibromas and plexiform neurofibromas in which malignant change has occurred or recurrence has been noted after surgical treatment, the tumors have been called malignant neurofibromas. Certain sarcomas which seem to be of neurogenic origin have been called neurogenic sarcomas.

Metastasis of malignant tumors of the peripheral nerves is not common; it occurred in only 20 per cent of the reported cases. The

A rare malignant tumor of peripheral nerves which is different from a fibrosarcoma has been termed a neuroepithelioma.

Although malignant tumors often extend locally along the sheaths of the nerves, they rarely give rise to distinct metastasis in nerves.

TREATMENT

As stated previously, the treatment of most tumors of the peripheral nervous system is surgical, and complete excision of the tumor and involved nerves should be followed by careful anastomosis of the nerve if

indicated. However, before outlining any type of treatment for tumors of the peripheral nerves, a careful examination should be conducted. This should include serologic tests for syphilis, routine tests for tuberculosis and a careful inspection of the skin of the body. The granulomas of syphilis and tuberculosis may simulate tumors of the peripheral nerves closely, a differential diagnosis, therefore, is important. In addition, a careful neurologic examination should be

subcutaneous fat. The tumor and the attached nerve should be exposed. If the tumor seems to be in the skin (glomus tumor), it is necessary to excise only the portion of the skin containing it. Subcutaneous tumors such as lipomas, should be excised, however careful inspection of the adjacent nerve usually will determine whether or not it is involved. If a neurofibroma involves the entire nerve (Fig 162, a), it is necessary to divide the nerve above and below the tumor and

Fig 165—Penneural fibroblastoma of the median nerve before during and after removal

made in order to determine any definite regions of anesthesia and any atrophy or weakness of the muscles. One should make a final inspection in an effort to differentiate primary tumors of nerves and other conditions resembling them. Many of these tumors exist for years without causing any discomfort or disability. As soon as they tend to cause pain along the nerves or show any definite increase in size, they should be removed surgically and examined microscopically. Under either regional or general anesthesia, an incision should be made through the skin and

subsequently to anastomose its divided ends with interrupted silk sutures inserted through epineurium. Fine tantalum wire has been used instead of silk as a suture material and has been found to cause less tissue reaction about the suture line. Plasma glue has also been used to join the divided ends of the nerve with tension sutures of tantalum wire. This latter technic is being developed and gives promise of usefulness especially in the smaller nerves and where there is little or no tension. If only part of the nerve is involved the fibers that are involved should

be carefully dissected free from the tumor and from those that are not involved. The tumor should be excised (Fig 16^o b) and the involved nerve should be anastomosed. A specific nerve sheath tumor or perineural fibroblastoma can be dissected from within the nerve fibers (Fig 16^o c). Incision of the outer sheath will allow close inspection of the tumor. As soon as it can be determined that no nerve fibers enter the tumor and that there is a line of demarcation between the tumor and the surrounding fibers, silk tension sutures should be placed in the tumor and by means of traction exerted with these sutures the tumor should be dissected from its bed within the fibers (Fig 163).

A traumatic neuroma should be excised and the ends of the nerve approximated (Fig 16^o d). A tumor arising in the divided ends of a nerve should be excised. Care should be taken that a sufficient portion of the growth is removed in order to allow for the approximation of normal looking fasciculi (Fig 16^o e).

The treatment of all tumors of the peripheral nerves is surgical. It consists of complete excision of the tumor and involved nerve and anastomosis of the cut ends of the nerve wherever possible.

Recurring or malignant tumors should be treated with excision and probably with radiotherapy, although most of these tumors are radioresistant. In cases in which there is extensive involvement or recurrence the entire extremity should be amputated.

SUMMARY

Hyperplastic growths following injury are represented by the traumatic neuromas. Hypertrophy of tissues rich in nerves probably explains the neuromyoarterial glomus. The pigmented mole has been included in the tumors of the sensory nerves of the skin. The tumors arising from the sheaths of the nerves have been designated as perineural fibroblastomas; they are benign and have a characteristic morphologic structure, but the etiologic factor is unknown. The true neurofibromas that involve both the sheaths and the nerves are part of a widespread disturbance of the nervous system that is known as von Recklinghausen's disease. A malignant tumor of a peripheral nerve usually de-

velops from a neurofibroma without any known cause.

TRIGEMINAL NEURALGIA

(Tic Douloureux, Trifacial Neuralgia, Foltz's Disease, Epileptiform Neuralgia, Neuralgia Major, Prosopalgia)

Definition.—Trigeminal neuralgia is a disease of unknown etiology, characterized by paroxysmal excruciating pain of sudden onset in the area of distribution of the fifth cranial nerve, which may be initiated by the stimulation of dolorogenic zones. The disease has a chronic clinical course interrupted by remissions.

Etiology.—This disease occurs most commonly in patients in the fifth, sixth and seventh decades of life. The youngest patient in a series of 444 cases was twenty-one years of age and the oldest eighty-three years. Of these 444 patients, 265 were females and 179 were males.

Although cases of the teeth is a disease of comparatively modern times, trigeminal neuralgia has been associated since the thirteenth century with the supposition that the teeth are involved. The treatment of trigem-

inal neuralgia is usually shared between the dentist and the physician. The pain may appear to originate in a tooth and though it is perfectly sound the patient insists on extraction. No definite etiological relationship can be established between carious teeth or any trauma which might attend their extraction and the pain of trigeminal neuralgia.

Other possible foci of infection such as the tonsils, ears and sinuses have been thought of as possible etiological agents but the removal of these infections has never been followed by lasting relief from the pain. The increased susceptibility of some persons to herpes labialis has also been investigated in relation to the occurrence of trigeminal neuralgia but without definite results.

That many of these patients have advanced signs of arteriosclerosis and that many suffer from hypertension is apparent from a study of any large series of patients but these instances are balanced by those patients whose blood pressure is within normal limits and whose arterial system is quite elastic.

Of the 444 patients with typical trigeminal neuralgia six showed definite symptoms of multiple sclerosis. Parker has described four such cases and in one found two sclerotic plaques in the pons at the point of emergence of the sensory root on the side affected. The sclerotic process extended outward a short distance within the substance of the root. The gasserian ganglion and peripheral divisions showed no pathologic changes.

Cases of the petrous portion of the temporal bone tumors or aneurysms in the cerebellopontile angle and osteomas of the middle fossa of the skull among many other diseases whose number is legion have been cited in the literature as probable etiological factors but as yet proof is lacking.

Pathology.—Examinations of the gasserian ganglion, portions of the sensory root and the peripheral branches of the trigeminal nerve have been made many times and by many different investigators without finding pathologic changes of significance. The lesion in trigeminal neuralgia whatever its nature may be is not a destructive one because of the absence of degenerative findings in the cells of the ganglion or in the peripheral or sensory root fibers and the total lack

of loss of sensation to any modality in the cutaneous distribution of the nerve.

The vasomotor symptoms which are characteristically present during the attacks of terrific pain have led some to implicate the sympathetic nervous system but again no definite gross or microscopic pathologic lesions have been described.

The presence of tumors or aneurysms which self-producing pressure on the gasserian ganglion or sensory root would lead to definite symptoms indicative of a destructive lesion in addition to the pain which would be produced. This combination of symptoms would immediately suggest that the case was one which should be diagnosed as some other condition than trigeminal neuralgia.

Symptoms.—Though this painful and intractable disease of the face may have been encountered it was not described as an entity until John Fothergill wrote his monograph *Of a Painful Affection of the Face* in 1776.

The onset of the pain of this disease is sudden and unforgettable. The patient experiences a lightning like jab of pain in his upper or lower gums at the side of the nose in the upper or lower lip or on the cheek beneath the eye. More rarely the first pain may be felt in the ophthalmic area of supply. When questioned years later the patient may describe with vivid accuracy with what task he was busied at the time of the onset of the pain. One person had just sat down to a Thanksgiving Day dinner, another was in the act of hanging out her freshly washed clothes and a third startled the audience and players in a theatre by her piercing scream. The initial pains are usually of very short momentary duration and are usually described by the patient as 'jabs' with a red hot poker or sharp knife. This series of pains may disappear just as suddenly as it came and the patient again feels perfectly well. If the pain occurs in the upper or lower gums it is attributed rather naturally to a tooth and in the mind of the patient this apparently localizes the pain accurately. Days, weeks, months or years later and though the guiltless tooth may have been removed the pain just as suddenly returns. The duration of the pain usually increases, it may radiate to another division of the nerve and the proxym may have a climax (sometimes

likened to the explosion of a bomb within the face) but still the onset and termination are dramatically abrupt.

If the patient is examined carefully, dolorogenic zones or the trigger areas of Patrick will be found. These are areas on the skin on the mucous membrane of the cheek on the side of the tongue on the gums on the upper or lower lip at the angle of the nose in the nares or anywhere within the distribution of the fifth nerve stimulation of which will initiate a typical paroxysm of pain. These trigger zones are quite characteristic of trigeminal neuralgia and constitute one of its most prominent symptoms. A light breath of air on the cheek the slightest touch on the lip or any movement of the face such as laughing talking eating sneezing or blowing the nose will start the pain. In many cases patients cannot stand the exacerbating pain occasioned by washing or shaving the affected side of the face and often one may see several weeks' collection of sebaceous secretion and dirt which has been left untouched on the patient's face. It is not uncommon to see patients who are dehydrated and emaciated because of their inability to take food or fluids without initiating paroxysms of pain the anticipation of which has seemed unbearable.

Patients behave differently during the attacks. With some the affected side of the face is screwed up tightly with the eyelids closed with others the jaw may be fixed wide open and saliva may drool from the mouth. In other patients tears stream from the eyes and they perspire freely. Some place a hand firmly on the cheek in an effort to stop the pain while some place their hand in a protective attitude beside the face but dare not touch it. Others rub the face briskly during the attack and so hard that the skin may be worn off.

The patient is usually free from paroxysms of pain at night no doubt because he is quiet and no facial movements are made. In some however the attacks continue night and day and no relief is obtained until the severity of the attack abates and an interval of freedom from the pain returns. These intervals of freedom may vary from complete relief to a condition in which the paroxysms of severe pain have disappeared and only short electric shocks of pain with long inter-

vals of freedom between are present. Some patients never lose the sensitiveness of the face even though stimulation of the trigger zones does not bring on the pain and the attacks are in complete abeyance.

The disease becomes more chronic as the years go by the intervals of freedom between attacks become shorter although the severity of the pain may have become somewhat less. Invariably the pain persists relentlessly and in former years before modern methods of treatment were known such often terminated the disease. In one instance in this series the patient seventy-two years of age suffered with the pain for thirty-six years before finding complete relief.

The pain of trigeminal neuralgia never radiates across the midline although both of the trigeminal nerves may be affected. Bilateral trigeminal neuralgia is not common however and in practically every instance several years elapse before the opposite side becomes involved. In the writer's series of cases only one case of bilateral trigeminal neuralgia has been observed.

Diagnosis.—The picture of agony presented by a patient suffering from a paroxysm of pain of trigeminal neuralgia is unforgettable and is not reproduced in all of its characteristics by any other disease which alone corroborates the diagnosis of trigeminal neuralgia. Stimulation of the trigger zone will produce a paroxysm of pain when the patient is in the throes of an attack. The patient commonly locates these areas for the examiner but they are not difficult to find. The remainder of the physical examination usually discloses nothing with direct bearing on the diagnosis.

The patient's story of the onset of the pain the exact location radiation and character of the pain are so striking and so definite as to be impressive. It is seldom indeed that a patient does not remember the exact situation and conditions under which the very first attack occurred and this is an important diagnostic fact.

The pain of sinus disease is not paroxysmal in character it is a heavy, severe neuralgic type of pain which occurs usually in the later hours of the day and as the sinus fills with secretion the pain becomes worse. There are no striking intervals of freedom

from pain. Toothache differs from it in many particulars but here again the paroxysmal climatic and explosive character of the pain of trigeminal neuralgia serves to make differentiation rather simple.

Glossopharyngeal neuralgia is a disease similar to trigeminal neuralgia in every respect except that it involves the ninth (glossopharyngeal) cranial nerve. The attacks of pain are alike as are the onset and course of the disease. The trigger zone is most commonly situated on the anterior pillar of the tonsillar fauces and stimulation of this area with a cotton applicator will initiate the pain. The pain is felt just below the angle of the jaw on the side of the throat and below the ear; it spreads upward toward the ear and toward the cheek. Coercion of the trigger zone will produce almost immediate relief from pain and is an accurate method of differentiation. Swallowing and eating are the most active stimulating factors in this disease. The distribution of the pain is the one point which differentiates it from trigeminal neuralgia during the period of a paroxysm of pain.

Tumors of the gasserian ganglion or of the cerebellar pontile angle and aneurysms of the internal carotid artery may produce severe pain in the face but the pain is of longer duration and does not have such an abrupt onset and termination. Moreover rather soon these lesions become destructive in nature and areas of sensory loss to one or more modalities of sensation may be found on examination of the trigeminal cutaneous distribution. As these tumors progress either cranial nerves are involved or other symptoms of intracranial tumor appear.

Deep boring pain in the maxilla and cheek has been ascribed by many rhinologists as due to neuralgia of the sphenopalatine ganglion. Cocaine solution may be placed on the mucous membrane of the nose just posterior to the middle turbinate where the ganglion will be affected and relief from the pain will serve as an accurate method of differentiation.

Though not common, ticlike pains may occur in the distribution of the fifth nerve and differentiation from the type of pain alone may be impossible. A careful neurological examination of the pupil reflexes and sensation will point to the correct diagnosis.

Malignant growths of the face and mouth may by extension involve the fifth nerve and its divisions and produce a severe agonizing pain in the face but differentiation from true trigeminal neuralgia is not difficult. The sensory root of the trigeminal may be severed to give these unfortunate patients relief.

There is a group of patients who complain of pain in the face which is not characteristic of trigeminal neuralgia and trigger zones are absent. Careful search for etiological factors in these cases may not be successful and relief from the pain cannot be secured by any of the common analgesic drugs. It has become the custom to group these cases under the term atypical neuralgias of the face because of a lack of knowledge concerning the correct diagnosis.

Prognosis and Course.—The course of trigeminal neuralgia is characterized by intervals of freedom from pain which are as abrupt in their onset as is the initiation of the pain. These may vary in length from days and months to years without any definite cause although it is customary for the patient to associate freedom from the pain with the last therapeutic method which has been tried. Invariably the pain returns to last an indefinite and usually a longer period of time made unbearable by a more agonizing and severe pain. As far as is known no case of trigeminal neuralgia has ever ceased spontaneously although intervals of many years between attacks have been recorded.

Treatment.—In an occasional case in the early part of its course when the severity of the attacks of pain is slight, medicine may give relief but in the majority of patients drugs fail to control the excruciating pain of trigeminal neuralgia. The usual analgesics are of little value though in combination with other hypnotics some slight relief may be obtained. Often morphine alone does not help but in combination with hyoscine temporary relief and sleep may be produced. In some instances inhalations of trichloroethylene may be of help although it has been the writer's experience that as time goes on relief becomes less sure and complete.

Many claims have been made for the effectiveness of injections of thiamine chloride, nicotinic acid, insulin and liver extract

over long periods of time. Improvements which occur following such treatments must be carefully differentiated from natural remissions of the disease. Most patients usually come to the surgeon eventually for relief.

In 1890 Rose excised the superior maxilla. Trephined the base of the skull with the foramen ovale as a cen-

ter for the temporal bone by means of an omega shaped flap of skin, muscle, perosteum and bone. This procedure was known as the high temporal operation in contradistinction to the method proposed first by Cushing¹ and later by Lexer² in which the line of incision was somewhat lower. These suggestions concerned only the means of reaching the ganglion to excise or avulse it. Because of the high mortality resulting from avulsion of the ganglion, operative procedures were limited for a time to division of the peripheral branches involved.

Fig. 164—*a* Location for the skin incision *b* opening in the squamous portion of the temporal bone and elevation of the dura mater over the temporal lobe to expose the middle meningeal artery *c* the point of section of the posterior root between the pons and the Gasserian ganglion *d* location of the middle meningeal artery and the exposure of the mandibular division in the foramen ovale *e* separation of the dura mater of the temporal lobe from the dural envelop along the ganglion and the line of incision in the envelop *f* posterior root is downward and outward to separate it from the motor root before division *g* divided ends of the posterior root posterior to the ganglion

ter and curetted away the Gasserian ganglion. At about the same time the elder Edmund Andrews among others exposed and excised the ganglion through the pterygoid fossa. These radical operative procedures were followed by an extremely high mortality. In 1891 Horsley suggested and performed division of the trigeminal nerve posterior to the ganglion and although he stated that "the operation presented no special difficulty beyond that of being very tedious" the patient died seven hours later of shock. In 1892 Hartley and Krause simultaneously advocated an approach through

Such incomplete measures were almost always followed by regeneration of the avulsed nerve and by attacks of pain in one of the remaining branches so that further surgical measures became necessary.

In 1901 Frazer divided the sensory root posterior to the Gasserian ganglion following a suggestion made by Spiller in 1898 that the fibers of the sensory root when divided between the ganglion and their entrance zone into the pons will not regenerate. It has been proved experimentally that regeneration of the sensory root never occurs after it has been divided at that point.

It is the fundamental principle on which the present day surgical treatment of trigeminal neuralgia is based.

At about the time when the mortality of surgical procedures was admittedly high and when the conclusive evidence of Spiller and Frazer was not yet accepted widely, Pitts and Verger and subsequently Schlosser advocated alcohol injection of the deep foramina of exit of the three divisions of the trigeminal nerve from the skull. The effect of the alcohol is to produce a local destruction by coagulation of the nerve fibers at the point of injection. This is followed by degeneration below that point to the periphery. However, as long as the cells of origin within the ganglion are intact a new nerve fiber will begin to grow downward and conduction within the nerve may be expected to return within from a few months to two years. In addition it may be realized that injections are not uniformly successful even in the hands of surgeons who have had a wide experience.

At present surgical approach to the gasserian ganglion and sensory root is made through the temporal bone at the level suggested by Cushing and Leach. However, the incision is a longitudinal one which extends upward for about 3 inches from the pretragal tubercle on the zygoma (Adson). A simple trephine opening is made through the squamous portion of the temporal bone and this is enlarged with bone-biting forceps. The method of making a large flap of muscle, periosteum and bone is quite unnecessary. The operative opening is enlarged downward as far as possible rather than upward, since the field is better exposed thereby and less retraction of the temporal lobe of the cerebrum is necessary. When the dura mater is raised by wet cotton sponge dissection from the floor of the middle cranial fossa it may become necessary to identify several landmarks. These are (1) the foramen spinosum through which the middle meningeal artery enters the cranial cavity, (2) the foramen ovale through which the mandibular division exists from the skull and (3) the gasserian ganglion with its sensory root. The operation is performed under local anesthesia until the ganglion is exposed. At that stage a light ether anesthesia is continued until the root is severed. The patient is awake before leaving the operating room and is relieved immediately of the pain. Total section of the sensory root brings about a sensory loss for pin prick, cotton wool touch and temperature stimuli over limited areas. (See Postoperative Care.) Deep pressure sense in the face is conserved in the facial nerve.

Recent refinements in technique proposed by Frazier,⁴ Stookey⁵ and others have made it possible to perform a subtotal section of the sensory root fibers. If the pain has been limited to the maxillary and mandibular divisions it may seem advisable to conserve the ophthalmic portion of the root. As Davis and Haver⁶ have shown since the fibers of the root enter in their course from the brain stem to the ganglion and anastomose freely at the hilus of the ganglion, it is necessary to exercise care as to the exact point at which subtotal section is performed. Otherwise fibers may be conserved in which pain has been present and relief may not be as successful as is possible. Another meeting in technique is that which conserves the motor root. This structure may be identified easily, and if the superior medial edge of the ganglion is drawn downward and laterally as Adson has suggested, the motor root will separate from the overlying sensory root quite easily.

In 1932 another approach to the sensory root by a suboccipital craniotomy was suggested by Dandy⁷ on the basis that section of approximately half of the sensory root near the pons results in complete relief of pain but with slight sensory changes in the face and that this operation often discloses small tumor masses or aberrant blood vessels which are etiological factors in the production of the pain. Experimentally and clinically it has been shown that the sensory loss from division of the root near the pons and near the ganglion is the same. Further, the possible surgical accidents which may occur in the important cranial nerves in the posterior fossa which must be exposed by a suboccipital approach is an important matter not to be regarded lightly, particularly since several serious postoperative complications of irreparable damage to the cerebellum have been observed following this operation by various neurological surgeons over the country.

Sjöqvist⁸ has proposed section of the bulbospinal trigeminal tract at the level of the lower half of the olive which produces an ipsilateral anesthesia for pain and temperature with preservation of sensibility to touch stimuli. The operation is technically more complicated than the Adson subtemporal preganglionic section of the sensory root and

a frequent complication is paresis of the recurrent nerve

Postoperative Care—Certain conditions may be present following an operation for trigeminal neuralgia which must be explained clearly beforehand to the patient. None of the approaches in gravity the excruciating pain from which the patient suffers. In the order of their importance these conditions are (1) lesions of the cornea (2) facial paresis (3) paresthesias (4) difficulty in mastication and (5) a feeling of fullness in the ear.

Involvement of the corneal epithelium occurs as the result of a direct injury to the insensitive cornea. It is necessary therefore for the patient to exercise more than ordinary caution in the care of his eye. He should wear glasses or goggles when exposed to a strong wind or to dust and cinders. Gauze or cotton should not be used to remove foreign material from the eye because of the danger of injuring the corneal epithelium. The patient must be instructed to irrigate the eye using either an eye dropper or an eye cup with sterile water twice daily and to close his eyelids more frequently than he has been accustomed to in order to lubricate the corner with the normal conjunctival secretions. Boric acid solution and other eye washes irritate the eyes of these patients. While in the hospital the patient is instructed carefully in the care of his eye and is made conscious of the fact he must protect the cornea from gross trauma. Dressings are not used in an effort to keep the eyelid closed; they are difficult to hold in place and add a definite hazard to the safety of the cornea.

If the cornea becomes ulcerated the eye may be closed by suturing the eyelids together until the cornea is healed. However if the patient is instructed to report the moment the eye becomes red and if he is then told to keep the eyelids closed voluntarily to irrigate the eye with sterile water and to continue this simple treatment until all redness has disappeared usually within forty-eight hours all signs of inflammation will disappear.

Paralysis or paresis of the facial muscles may follow division of the sensory root of the fifth nerve and all of the facial muscles on the affected side are involved. It occurs

in about 2 per cent of the cases and may be present immediately after or may appear some days following operation. Its occurrence has been ascribed to trauma within the pons produced by avulsion of the sensory root to the slow oozing of incompletely controlled bleeding and to traction on the greater superficial petrosal nerve, a branch of the geniculate ganglion of the facial nerve. The latter is the most likely and accurate explanation since this nerve crosses the petrous portion of the temporal bone and may be injured as the dura mater is raised from the floor of the middle fossa. In any case the facial weakness recovers much as does a typical Bell's palsy. Massage and electrical stimulation of the muscles of the face plus the use of small adhesive strips to keep the muscles from sagging have aided greatly in obtaining a prompt recovery.

The paresthesias complained of following operation include burning and sticking sensations in the conjunctiva of the eye, a feeling described as if the face were held in a plaster cast, formication, numbness and coldness. It may be surmised that descriptions of the resulting sensory loss and the severity of the discomfort produced depend entirely on the mental make-up of the patient. The nervous person usually hothouses a great deal about these vague sensations for several weeks or months. He becomes obsessed with the idea that the relief from his excruciating pain cannot be permanent and interprets these sensations as forerunners of an impending attack. When he is finally convinced that his paroxysmal pains will not return he soon forgets about the paresthesias.

Difficulty in mastication does not occur when the motor root is preserved and therefore there are only a few patients who complain of being unable to open their mouth as widely as before operation and of difficulty in chewing their food. There are a few instances in which it is difficult to isolate the motor root without prolonging the time of operation considerably and in a patient of advanced years one must weigh the problem carefully. Regardless of whether or not the motor root is spared many patients complain of losing particles of food between their teeth and cheek on the affected side. In view of the loss of sensation within the mouth

the explanation of this fact is easy to understand but without exception a satisfactory adjustment to this situation is made rapidly.

A rather small group of persons complain of a feeling of fullness or heaviness in the auditory canal following operation. Careful examinations of the tympanic membrane and external ear usually offer no explanation for this symptom but fortunately it soon disappears. Adson has suggested recently that it is caused by a collection of cerebrospinal fluid which escaped during the operation within the internal auditory canal.

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia is a disease which resembles trigeminal neuralgia in that the pains are spasmodic, excruciating, lancinating and radiating. However, in glossopharyngeal neuralgia the pains are projected along the distribution of the ninth cranial nerve whereas in trigeminal neuralgia they are projected along the distribution of the fifth cranial nerve. In glossopharyngeal neuralgia the trigger zone is placed in the tonsillar fossa and the darting pains are projected toward the ear usually terminating in the tympanum. The pains are precipitated by yawning, swallowing and talking but they are not precipitated as they are in trigeminal neuralgia by rubbing the face.

Weisenburg in 1910 was the first to de-

scribe the syndrome of pain produced by a tumor pressing on the ninth nerve. Oppenheim described a case in which there was paralysis of the ninth nerve and in which objectively there was thermesthesia and paralysis of the soft palate and pharyngeal muscles on the same side. He stated however that the tactile sensation was preserved. Sicard and Robinson, Harris, Doyle, Dandy, Stookes, Peet and the writer have reported experiences encountered in the treatment of glossopharyngeal neuralgia.

My first experience dates back to March 18, 1922 when a patient was examined who complained of a rather indefinite pain syndrome in the region of the tonsillar fossa, parotid area, ear and neck and for whom an injection of alcohol into the fifth branch had been without effect. Curiously enough the patient told us that temporary relief had been afforded when a local physician had cauterized his throat at a particular time; however this phenomenon did not have a great deal of significance to us because the pain was severe, resembling trigeminal neuralgia and involving the auriculotemporal branch and because the patient was not getting sufficient relief from palliative measures. I thought we were justified in carrying out a radical operation on the fifth nerve. I subsequently divided the sensory root on March 23. The patient received the usual anesthesia that follows division of the sensory root but in spite of this there was recurrence of pain when the patient awoke about a week following the operation. The pain continued to recur until I divided the glossopharyngeal nerve extracranially through a lateral cervical wound on April 23. This gave the patient complete relief until June 10, 1924 when he had a recurrence. This led to discontinuance of the peripheral operation and to the employment of intracranial nerve section proximal to the ganglion which I proposed in June of 1924 and carried out on November 6, 1925.

Etiology and Pathology.—The etiology of this disease is just as obscure as that of trigeminal neuralgia. It is rather curious that both diseases begin in middle life or later and that they both occur in cycles, with paroxysms of pain followed by intervals of complete relief. In both diseases no definite pathologic change has been demonstrated in the ganglions. Likewise in both diseases the pain is invariably initiated by stimulation of a trigger zone. It is generally assumed that the disease is the result of some pathologic change in the ganglion itself. However it is fair to postulate that these classic attacks of pain may be the result of some circulatory phenomenon, something akin to the periodic attacks of vaso-

spasm seen in the peripheral arteries in Raynaud's disease. It is barely possible, too, that these circulatory attacks, recurrent attacks of pain, may be the result of some allergic disturbance. The pains are so severe that they cannot be of functional origin and must be the result of a chemicopathologic disturbance in the central nuclei rather than in the peripheral ganglions of the nerve. One would like to look on both glossopharyngeal neuralgia and trigeminal neuralgia as a disease of the peripheral nerves, a type of neu-

tonsillar fossa. The pains are brought on more often by yawning and swallowing than by chewing and cannot be brought on by rubbing the face, only occasionally are they brought on by rubbing the ear. Glossopharyngeal neuralgia also differs from trigeminal neuralgia in that the pain is projected from the tonsillar region and pharynx through the neck to the ear, particularly to the tympanum. In glossopharyngeal neuralgia it will be observed that cocaineization of the pharynx will result in temporary cessation

Fig 165—Retraction of the cerebellum with lighted retractor exposing the seventh, eighth, ninth, tenth and eleventh cranial nerves

ritis, if this were true, however, then one would naturally expect to find definite paresthesia and anesthesia before any operative intervention, which evidence is lacking.

The temporary relief that follows cocaineization and extracranial avulsion is faintly suggestive that the disease is of peripheral nerve origin. The recurrence of pain with regeneration of peripheral fibers indicates that the seat of pain is not in the peripheral fibers. They carry afferent impulses to set off the painful reflex which includes spasm of the pharyngeal muscles and arteries.

Symptoms and Differential Diagnosis.—The pains resemble those of trigeminal neuralgia in their occurrence, duration, repetition and character, but they differ from those of trigeminal neuralgia in their distribution. The trigger zone is situated in the

of all attacks, but it will not alter the paroxysms when they are due to trigeminal neuralgia.

Palliative Treatment.—Injection of alcohol cannot be used in the palliative treatment of glossopharyngeal neuralgia, as it is used in the treatment of trigeminal neuralgia since the ninth nerve is too intimately associated with the tenth and eleventh cranial nerves and the cervical nerves and with the cervical sympathetic chain. Therefore, the only temporary procedure that has offered any palliative relief at all has been peripheral avulsion. Peripheral avulsion of the ninth nerve is a rather formidable procedure, and it is one that the writer has discontinued since the intracranial procedure can be carried out without any difficulty and it assures permanent relief.

At the onset of this disease most patients are not prepared to accept a formidable operation. It is therefore necessary that patients thoroughly understand the problem. They should be told that the paroxysms of pain will return and that permanent relief can be obtained by intracranial nerve section. Sedatives such as bromides, phenobarbital and trichlorethylene have a tendency to decrease the severity of the attacks. It is unwise to advocate continued use of morphine. If palliative measures fail to furnish relief, the radical procedure should be advised.

Technic of Intracranial Division of the Glossopharyngeal Nerve.—The exposure is that of unilateral suboccipital decompression. The patient is anesthetized through a Magill intratracheal tube with ether and then placed on a cerebellar upright frame. A straight lateral scalp incision is employed. The skin and muscles are reflected in the same manner as they are for cerebellar decompression and the bone covering the nuchal cerebellar lobe is rongeuired away. The dura is incised along the outer and inferior borders of the decompression. If the cerebellar lobe does not displace easily, one can drain the posterior cistern. Before elevating or displacing the cerebellar lobe, it is well to cover the dura and cortex with strips of cotton. The lobe of the cerebellum is then elevated with an illuminated retractor which exposes the seventh and eighth cranial nerves inferior to these and slightly more superficial the ninth, tenth and eleventh nerves will be seen entering the jugular foramen (Fig. 165). On closer observation the ninth and tenth nerves will be found to be short and to pass at right angles from the medulla, whereas the spinal accessory nerve is longer and will be seen to enter the foramen in an oblique course from below upward. The glossopharyngeal nerve enters the foramen at the rostral margin and is separated from the vagus nerve by a small dural band which is less than 1 mm. in width but which is definite enough to distinguish the ninth nerve from the tenth and to permit one to pass a small right angled Langdon knife between the fibers of the glossopharyngeal and vagus nerves allowing for sharp section of the glossopharyngeal nerve without injury to the vagus.

Results.—Pain is instantly and permanently relieved after intracranial section of the glossopharyngeal nerve. The sensations of taste on the one side of the tongue detected by the circumvallate papillae are lost. Tactile pain and thermal sense is lost in the upper half of the nasopharynx including both sides of the soft palate and tonsillar pillars. Since the motor innervation of the stylopharyngeus muscle has been included the soft palate will be seen to retract to the unoperated side. Immediately after operation the patient may complain that fluids return through the nose during the act of swallowing but he soon learns to overcome this. Their appreciation of the relief from pain appears to make the patients forget about the anesthesia for rarely do they complain of any discomfort.

SCIATICA

The term sciatica has come to include all painful conditions about the hips and thighs or any lesion that produces projection of pain along the sciatic nerve. Since sciatic pain may result from any number of lesions it is apparent that the origin of this pain must be located before any attempt is carried out to treat the condition.

The projection of pain along the sciatic nerve frequently accompanies hypertrophic arthritis and contractures of the iliotibial band. It is usually a common and persistent symptom in sacroiliac disease. It is frequently found to be an early symptom of tumor arising from the nerve roots of the cauda equina and in the filum terminale. The pain produced by intraspinal tumor is rather characteristic as it appears after the patient has been reclining for from four to six hours and disappears when he rises and walks about. As the tumor grows pain will be associated with loss of reflexes and with impairment of sensory and motor functions. Sciatic pain may result from anomalous bony and cartilaginous lesions of the lumbo-sacral portion of the spine, pelvic tumors, metastatic lesions in the lumbar portion of the spine and pelvic bones, neurofibromas within the sciatic nerve itself and vascular disease of the legs and feet due to thrombo-angitis obliterans and arteriosclerosis.

Protruded Intervertebral Disk as an Etiologic Factor—The cartilaginous lesions referred to in recent literature as protruded intervertebral disks or rupture and prolapse of the nucleus pulposus into the spinal canal appear to be the most common cause of recurring chronic sciatica. Although the lesion has been encountered for years I operated on my first patient with this condition in 1922. It was not recognized and diagnosed preoperatively until opaque oils were introduced into the spinal canal and were observed under the fluoroscope. In these cases roentgenographic findings revealed a filling defect in the column of oil opposite the lesion owing to the bulging mass produced by the protrusion of the nucleus pulposus. This protrusion compresses the nerve root between the cartilaginous mass and the bony structures surrounding the intervertebral foramen. The fourth and fifth lumbar roots on one or both sides are usually involved

and give rise to unilateral or bilateral extension of pain from the lumbosacral region along the course and distribution of the sciatic nerve.

The symptoms produced by this condition may vary in intensity depending on the character of the protrusion of the nucleus pulposus of the intervertebral disk. At the onset the protrusion may be small owing to the fact that only a few fibers of the annulus fibrosus have been ruptured but as recurring attacks take place more fibers are ruptured and a large bulging mass protrudes into the spinal canal. If attacks of sciatic pain continue to recur eventually the greater portion of the nucleus pulposus will have prolapsed through the annulus fibrosus and will give rise to a group of continuous symptoms. Injuries to the spinal column such as acute anterior flexions of the spinal column are common causes for the rupture of the annulus fibrosus and the partial or complete prolapse of the nucleus pulposus. This condition may result from a jump or fall in which the person lands heavily on his feet or buttocks. They also result from 'lifting' accidents in which a person feels something snap when he is lifting a heavy object. However it is surprising to encounter a goodly number of patients who complain of recurring attacks of sciatica but have not sustained any injury as far as they know. This phenomenon is probably explained by the presence of weakness in the annulus fibrosus, the ligamentous band which holds the intervertebral disk in place. This weakness which is due to thinness in the ligament is located on the dorsolateral surface lateral to the midline and lateral to the posterior longitudinal ligament since this is the site of most of the protrusions (Figs 166 and 167).

Pain is the characteristic phenomenon and often does not appear until hours following the injury. It consists of darting stabs in the lumbosacral region and usually is associated with muscular spasm and scoliosis with a shift of the trunk to the opposite side. In the more advanced cases pain extends along the course of the sciatic nerve. It gives rise to tenderness along the nerve and patients not infrequently complain of muscle cramps in the calf of the leg with darting pains extending to the outer surface of the foot. If

protrusion of the nucleus pulposus is almost complete, adjacent nerve fibers, usually those of the fourth and fifth lumbar nerves, may be compressed. This compression may give rise to involvement of sacral nerves and in turn to paresthesia along the anus and over the perineum, with disturbance of bladder and rectal functions. Small protrusion

control the pain. Undoubtedly many small injuries of the annulus fibrosus with protrusion heal spontaneously. However, when recurrent attacks continue to appear, it is evident that sooner or later a portion of the nucleus pulposus will ultimately prolapse through the rent in the ligament without prospect of spontaneous recovery.

Fig 166.—The mechanics involved in the rupture of the intervertebral disk with prolapse of the nucleus pulposus; a, a normal intervertebral disk; b, prolapse of the nucleus pulposus into the spinal canal; c, appearance of the ruptured intervertebral disk following removal of the prolapsed nucleus pulposus.

Fig 167.—The trauma and the resulting edema which develops within the compressed nerve root from the protrusion of the intervertebral disk.

sions of the nucleus pulposus usually give rise to short bouts of sciatica. Diminution of the symptoms is undoubtedly due to recession of the nucleus. This recession can be accomplished by placing the patient on a bed with a firm mattress and by using Buck's extension. Local heat will relieve the muscular spasm, and mild anodynes will

The neurologic symptoms, therefore, consist of localized pain situated in the lumbosacral region with extension of pain along the course of the sciatic nerve, subjective or objective paresthesia and anesthesia, depending on the size of the protruding cartilaginous mass. When the larger lesions are present, the achilles tendon reflex is im-

paired or absent Lasegues and Kernigs signs are always present. Muscular spasm in the lumbar region is usually present and is frequently associated with scoliosis and a limp. Studies of the spinal fluid frequently reveal an increase in the concentration of protein to more than 40 mg per hundred cubic centimeters. However if the lesion is of long standing the spinal fluid may be normal.

Differential Diagnosis—Although protruded intervertebral disks are a common cause for chronic recurring sciatica they are not the only cause of sciatic pain and in making a differential diagnosis the symptoms produced by neoplasms of the pelvis neoplasms within the spinal canal and those

Fig 168—Roentgenogram illustrating a filling defect in the lipiodol opposite the intervertebral disk between the fifth lumbar and the first sacral vertebra due to rupture of the disk with prolapse of the nucleus pulposus.

of the peripheral nerves, skeletal system and muscles must be kept in mind. Then too infections cannot be disregarded. Occasionally neuritis has developed though it is rather unusual when the sciatic pain is unilateral. Hypertrophic arthritis is not an uncommon cause for sciatic pain. However pain resulting from hypertrophic arthritis is usually not recurrent but continuous in contrast to the pain produced by a protruded disk which is characterized by recurrent rather than continuous attacks. The pain in the latter condition becomes continuous only when the nucleus pulposus has prolapsed through the rent in the annulus fibrosus and is unable to replace itself within the disk.

The history of injury, low back and sciatic pain associated with muscular spasm, scoliosis, an impaired achilles tendon reflex and a positive Lasegues sign is almost pathognomonic of a protruded intervertebral disk. These symptoms and signs are so characteristic of the lesion that the surgeon is justified in exploring the fourth and fifth lumbar disks surgically without myelographic studies. Of course it is needless to say that for every patient who complains of a group of symptoms suggestive of protrusion of a disk or fusion a thorough history, careful physical, laboratory and neurologic examinations and plain roentgenograms of the lumbosacral portion of the spinal column are required. In order to protect the patient further against errors in diagnosis consultations should be held by the orthopedic surgeon, neurologist and neurosurgeon since it is not infrequent that the orthopedic surgeon suggests a bone graft for the lumbosacral region in conjunction with removal of the protruded portion of the nucleus pulposus in order to support the spinal column when there are bony anomalies such as spina bifida occulta, sacralization of the fifth lumbar vertebra, early spondylolisthesis and active hypertrophic arthritis. Studies involving spinal puncture are of value but are not always necessary unless combined with a myelographic study. They are of course indicated if an intraspinal tumor is suspected.

Myelographic Study—The use of opaque oils such as lipiodol and pantopaque in fluoroscopic studies are distinct diagnostic aids (Fig 168). However since there is some suspicion that these oils may give rise to irritation to the meninges and nerve roots they should be removed following the roentgenologic study. Since this procedure subjects the patient to a rather prolonged examination under the fluoroscope the pneumomyelogram is employed in most cases at the Mayo Clinic. For the pneumomyelogram the cerebrospinal fluid is replaced by oxygen. The filling defect produced by the protruded disk is visualized in about 75 per cent of the cases. The test is not as accurate as the one in which the opaque oils are used. However there are certain advantages in using the pneumomyelogram since the procedure can be carried out

much more quickly than that in which opaque oils are employed, as it is not necessary to prolong the examination by removing the oxygen or air. Pantopaque and occasionally lipidol are employed when there is considerable doubt as to the presence and size of the protrusion or when a legal question is raised as to whether or not a protruded disk resulted from a given injury in an industrial accident.

Treatment.—The treatment for a protruded disk which is responsible for recurring attacks of sciatica is its removal. This is accomplished by one of two methods. In the beginning of this sort of surgical treatment, bilateral lumbar laminectomy was considered necessary. However, the usual

important not to injure the nerve root, to control hemostasis and to avoid injury to the dura and arachnoid (Figs. 169 and 170).

Since acute and chronic infections may be responsible for perineuritis and periradicularitis, as well as for the various types of arthritis, it is extremely important that thorough eradication of all foci of infection be accomplished. Heat in the form of hot packs, dry heat or diathermy usually is effective in controlling pain, but it is less effective, of course, when pain is due to tumor. Roentgenotherapy has been tried but has offered little or no relief.

Epidural injection for pain of the ganglionitis type is fairly successful and can be repeated innumerable times, depending on

Fig. 169.—The compression of the nerve root by the protrusion of the nucleus pulposus into the spinal canal and the relief of compression when the mass has been removed. *a*, protrusion of the nucleus pulposus through a rent in the intervertebral ligament, compressing the lumbar nerve root; *b*, removal of the ribbon like fibrocartilaginous nucleus pulposus; *c*, relief of compression of the nerve and dura following removal of the fibrocartilaginous mass.

type of laminectomy now employed consists of removing the ligamentum flavum at the interlaminar space over the lesion with sub-total unilateral laminectomy. This type of laminectomy consists of no more than the nibbling away of sufficient bone, that is, the lower border of the lamina above the lesion and the upper border of the lamina below the lesion to such extent that a finger can be introduced through the opening. This procedure affords ample space to retract the dura and nerve root in order to uncover the protruded mass prior to its removal. Love has frequently found that the removal of the ligamentum flavum has been sufficient to uncover and remove the protruded mass. In carrying out the operation, it is extremely

the relief obtained. During this period, while injections are being administered, foci of infection are eradicated and local heat is applied. The only explanation one can give of the beneficial effects of epidural injection is that novocain produces anesthesia, which of course relieves the pain temporarily and allows muscular spasms to subside. It is hardly possible that forceful injection of a fluid substance into the epidural space may result in some breaking down of adhesions about the dorsal ganglion, thus relieving some of the irritating influences which give rise to pain.

Sciatic pain due to sacroiliac disease is treated not only by removal of foci of infection but by the application of a sacroiliac

belt The pain is further ameliorated by the use of diathermy In severe cases patients require hospitalization during which time Buck's extension is applied to the lower extremities and a lumbar sling is placed under the lower part of the back to reestablish the proper lumbar curve Similar radical measures may be necessary to control sciatic pain resulting from hypertrophic arthritis

Ober in discussing low back pain with sciatic extension emphasized that contractures of the ilial band result from postural influences such as lying in bed for long periods during a serious illness He stated that they also result from unusual abduction and rotation of the hips such as those that

body If there is any abduction contracture the leg will remain more or less passively abducted depending on the shortening of the iliotibial band This band can be easily felt with the examining fingers between the crest of the ilium and the anterior aspect of the trochanter

Ober has advised two types of treatment for contractures of the iliotibial band which he and others believe are frequently responsible for low back pain and low back pain with sciatic extension When the symptoms are those of low back pain alone he stated that the symptoms may be relieved by stretching exercises carried out in the following manner

Fig 170—Photograph of specimen removed at operation (nucleus pulposus)

result from a frog like position maintained by certain orthopedic measures The diagnostic symptoms of contractions of the iliotibial band are limitation of motion muscle spasm tenderness over the lumbosacral and sacroiliac regions and posterior to and just below the greater trochanter sciatic scoliosis limitation of straight leg raising positive Ely's sign and functional scoliosis if the abduction contracture is unilateral

Ober suggested that the method of performing the test for abduction is as follows

The patient lies on his side with the thigh next to the table and flexed enough to obliterate any lumbar lordosis The upper leg is flexed at a right angle at the knee The examiner grasps the ankle lightly with one hand and steadies the patient's hip with the other The upper leg is abducted widely and extended so that the thigh is in line with the

The patient stands with the affected side about 2½ feet away from a table or some other convenient object which he grasps with one hand then, with his shoulder and pelvis in the same plane he bends the affected hip toward the table as far as he can his whole figure forming an arc This position is maintained for a few seconds and then repeated five times the first day and is increased once each day until the exercise is done twenty five times twice a day

In those cases in which there is a severe sciatic operation is indicated and the method of procedure is as follows

1 An incision is made from just below the crest of the ilium down to the tip of the trochanter directly over the contracted iliotibial band

2 The fascia lata is exposed forward as far as the anterior superior spine and backward to the edge of the gluteus maximus muscle The area of the greatest contracture of the fascia can be seen readily and felt easily

3 The fascia is now divided transversely from just below the anterior superior spine to the anterior border of the gluteus maximus muscle There is immediate separation of the cut edges for a distance of from ¾ to 1½ inches depending on the amount of contracture present If the operator now attempts to carry out the test [for abduction] described it will be shown that the thigh will completely adduct

In reporting the results obtained by the treatment suggested Ober reviewed the data concerning 340 patients treated by other surgeons and 75 patients treated by himself Of these 415 patients 84 (about 21 per cent) obtained no relief 17 (4 per cent) showed only partial relief and 314 (75 per cent) obtained complete relief The symptoms were relieved immediately or after intervals up to one year The average time before relief took place was about three months

spoken of as sympathicoblasts (sympathogonia) and neuroblasts and give rise to both the adult sympathetic ganglion cells and the chromaffin tissue of the body. This latter is located for the most part in the medulla of the adrenal gland but is found as well in the so called carotid, aortic and coeliac glands. Certain chromaffin cells are also scattered throughout the lower ileum and in the large bowel as the so called "gelben Zellen" of the crypts of Lieberkuhn. In view of this rather complicated pattern of development it is perhaps not surprising that one may find elements of varying degrees of maturity in the tumors arising from the sympathetic nervous system or chromaffin tissue.

NEURORLASTOMA

(Sympathicoblastoma Sympathogonioma)

A neuroblastoma is a highly malignant tumor arising from the undifferentiated primordial of the autonomic and chromaffin systems occurring predominantly in infancy and early childhood. Several of the reported cases having been congenital. Eighty seven per cent of Lewis and Geschichter's own series of 40 patients were under fifteen and about half were less than three years of age. On the other hand, Ritter and Meltzer have reported 3 instances of this tumor in persons over forty. By far the commonest site of the original growth is the adrenal gland, but such tumors have also been encountered arising from the paravertebral sympathetic chain, in the thorax, in the uterus or the upper jejunum and in connection with the coeliac ganglion.

Pathology.—The primary growth in neuroblastoma is occasionally very large but from adrenal tumors so small that they appear merely as a bulging of the gland while spread metastases reaching considerable size may originate. The larger tumors are nodular and firm and are surrounded by a thin layer of fibrous tissue. They are very vascular and on cross section are glistening white with an admixture of the various chromatic changes of old hemorrhages or of necrosis. Microscopically they are for the most part composed of small cells about the size of lymphocytes containing relatively large nuclei certain of which tend to be arranged in the characteristic rosettes. The cytology

TUMORS OF THE SYMPATHETIC NERVOUS SYSTEM

Embryologically the sympathetic nervous system is derived from the medullary epithelium by way of ganglionic crest cells which migrate outward to the sites of future ganglia and plexuses. In the course of this process the cells themselves undergo a series of developmental changes from primitive undifferentiated cells, through the types

is often mixed, comprising more mature elements, such as ganglion cells, and the degree of malignancy conforms roughly to the immaturity of the predominating cells. Metastases, occurring first by the lymphatic route in the neighboring nodes, are later found in the liver and more distant organs, including the skeleton.

Symptoms and Signs.—The commonest findings include an abdominal mass, which may be the tumor itself or a very markedly enlarged liver, fever and anemia. However, from the accumulated cases several clinical types may be recognized which depend somewhat on the site of the original growth, but more especially on the extent and dis-

tribution of the metastases. Thus, in a small number the adrenal gland may be largely replaced by the growth, producing a picture of Addison's disease with asthenia and cutaneous pigmentation. In another group the tumor, arising in the thorax from the paravertebral chain, may enter the spinal canal, producing the syndrome of a mediastinal or hour glass tumor. In other instances the syndrome may simulate acute rheumatic fever, with high fever and multiple joint involvement.

these, the so-called Hutchinson's syndrome is characterized by swellings involving the bones of the skull, unilateral or bilateral ophthalmos and discoloration about the eyes, and, more rarely, signs of an intracranial lesion including papilledema, convulsions or paralysis. An abdominal tumor may be felt but is not a feature of this syndrome. Necropsy in these cases usually shows a retroperitoneal neuroblastoma, most often originating in the left adrenal gland with widespread metastases to the skull and intracranial structures.

In the second syndrome, as described by Pepper, the most prominent finding is a marked enlargement of the liver, with syn-

Fig. 171—Neuroblastoma

Fig. 172—Ganglioneuroma

tribution of the metastases. Thus, in a small number the adrenal gland may be largely replaced by the growth, producing a picture of Addison's disease with asthenia and cutaneous pigmentation. In another group the tumor, arising in the thorax from the paravertebral chain, may enter the spinal canal, producing the syndrome of a mediastinal or hour glass tumor. In other instances the syndrome may simulate acute rheumatic fever, with high fever and multiple joint involvement.

The two pictures encountered most frequently were originally described as due to sarcoma, before the true nature of the tumor causing them was recognized. The first of

toms referable to the abdomen. Necropsy most commonly shows a tumor arising in or near the right adrenal gland with massive infiltration of the liver.

Course and Treatment.—These tumors are rapidly fatal; only a single patient having been successfully operated upon, and this instance the tumor was still confined to the adrenal gland. Radiation is usually ineffective, although softening and shrinking of the tumor may follow its use in some cases.

GANGLIONEUROMA

This relatively benign tumor originating from sympathetic ganglions is found usually along the paravertebral chain, either in the

chest or abdomen Heuer and Andrus were able to collect reports of 68 cases in which the growth was intrathoracic It is encountered most often in children about three-fourths of the patients being in the first decade of life The tumor is well encapsulated and of firm consistency gray on section with irregular lobulation it is relatively avascular The tumor may reach considerable size to measure as much as 17 cm in largest diameter and to weigh 2 kg Microscopically it is seen to be composed of rather coarsely arranged fibrous tissue nerve fibers both medullated and non medullated and multipolar ganglion cells The latter vary in number in different tumors and many of them show signs of degenerative changes such as vacuolization

The gangliomas are for the most part benign but like the other tumors of this group may contain such a variety of cells that they must be regarded as potentially malignant Clinical experience confirms the difficulty of estimating the future course from the gross appearance Thus these tumors have been known to be present for sixteen years before being successfully removed and in other cases incomplete extirpation has failed to cause recurrence In still other instances however metastases have occurred in lymph nodes soft parts and bones In at least one case the tumor was found distributed diffusely in the subcutaneous tissue

Symptoms and Signs—Despite the very considerable size which they may attain the ganglioneuromas grow quite slowly and produce but few symptoms save for those of pressure on the ganglions or nerves from which they arise such as a Horner's syndrome or absence of sweating in a given zone Since a variety of tumors may press upon nerves or ganglions however the diagnosis is rarely made before operation or necropsy

Treatment—In view of the uncertain course operation on these tumors is advisable whenever their presence is suspected

PARAGANGLIOMA

These tumors springing from that branch of the neuroblast tree which gives rise normally to the chromaffin tissue of the body are the most common of all the tumors of the sympathetic nervous system They appear most frequently in the medulla of the

adrenal body in the carotid body and in the appendix caecum and small intestine as the so-called carcinoid or argentaffin tumors The microscopic pictures vary widely but in each group certain characteristics are discernible

Tumor of the Carotid Body—Tumor of the carotid body represents one of the most important tumors of the sympathetic nervous system not because of its frequency since it is by no means common but rather because it is usually recognized and being relatively superficial has been frequently attacked surgically Rather rare in patients under twenty these tumors are seen most often in patients from forty to sixty years of age Usually the growth is gradual one of the reported tumors having been present for thirty years before being removed but many patients have noted a more rapid increase in size of the tumor in the months preceding treatment

Symptoms—This tumor is usually symptomless until it causes pressure upon the surrounding structures such as the neurovascular bundle or neighboring nerves Thus may occur with even comparatively small tumors the vagus being most commonly involved and then in order of frequency the hypoglossal cervical sympathetic glossopharyngeal and spinal accessory nerves

Pathology—Generally the carotid body tumor is firm nodular and of even consistency throughout with the cut surface presenting a yellowish or orange color varying to red depending on the vascularity A well defined fibrous capsule is usually evident The neighboring lymph nodes may be attached to the tumor but are seldom invaded by the growth Microscopically two general topographical patterns predominate in one of which the cells are arranged in nests or alveoli while in the other the cell growth is so intimately arranged about blood vessels that it is spoken of as perithelioma In both types the cells themselves contain a relatively large amount of eosinophilic cytoplasm and one or more dark staining nuclei Giant cells are also observed and in many instances active mitosis irregular cell growth and even invasion of the capsule can be seen Approximately 50 per cent of these tumors must be considered as malignant

Diagnosis—A tumor of the carotid body

should be suspected when there is a single, smooth, non-tender mass located at the bifurcation of the carotid artery, more movable laterally than vertically. To these signs may be added in some cases a transmitted pulsation and bruit and thrill, as well as signs of pressure on some of the neighboring nerves. The carotid artery is usually displaced laterally and comes to lie in a groove on the outer aspect of the tumor.

Treatment—The ideal treatment of a tumor of the carotid body is complete surgical removal, a procedure which is complicated in about 50 per cent of the cases by the necessity of removing also a segment of the carotid artery. Almost all the deaths in

cept for the complications of interruption of the internal carotid, cures are the rule. Recurrences or metastases are quite rare.

Pheochromocytoma.—Of recent years attention has been drawn to certain paragangliomas, the so-called pheochromocytomas, of the adrenal medulla which are composed of mature chromaffin cells of a type capable of producing adrenalin. The clinical course in these cases is characterized by intermittent attacks of hypertension associated with other constitutional symptoms, such as precordial pain, tachycardia, pallor or flushing and profuse perspiration. The picture may simulate that of hyperthyroidism and attacks are occasionally precipitated by

Fig 173—Malignant carotid body tumor

Fig 174—Pheochromocytoma

recorded cases have followed ligation of this vessel and have been due to cerebral ischemia. Before undertaking the extirpation of the tumor, therefore, every effort should be made to prevent such complications through the application of intermittent pressure for increasing lengths of time to the artery proximal to the tumor, until the patient can tolerate obliteration of the vessel for a long period without faintness or loss of consciousness. In a smaller number of cases the jugular vein must also be sacrificed, and still more rarely the vagus nerve will be found involved in the growth. These tumors are usually quite radioresistant, but x-ray has been effective in a few of the reported cases.

The surgical results are excellent, and ex-

pressure in the region of the tumor. These tumors may occur at any age but are rarely seen in children.

Pathology—Pathologically the tumor is usually well encapsulated but extremely vascular. The cells have clear or eosinophilic cytoplasm, with small round nuclei and a distinct affinity for the chrome stains. A high content of adrenalin can often be demonstrated by means of physiological tests.

The tumor is rarely palpable and since it is found bilaterally in about 15 per cent of cases, the localization may depend on operation although perirenal air injection may be helpful by demonstrating a rounded mass in the region of the adrenal gland.

Heuer and Marshall were able to collect

reports of 108 such cases from the literature up to 1941, in most of which the tumor had been found at autopsy, but at least 30 of the patients had been operated upon and the tumor successfully removed in 24 instances. While these cases present many difficulties, the treatment is unquestionably surgical and has produced spectacular results in some cases.

"Carcinoid" Tumor.—Obendorfer, in 1907, separated a group of neoplasms from the true carcinomas of the gastrointestinal tract and gave them the name of "carcinoids." These are believed to arise from the "gelben Zellen" described by Schmidt and occur most often in the appendix, where they are found once in every 200 to 500 operations.

Fig. 175—Carcinoid of the appendix

Less often they are encountered in the small bowel or even in the stomach. The location of the growth is of some importance, since those of the small bowel are definitely more malignant, while the appendiceal carcinoids are benign.

In the appendix the tumor appears as a localized swelling of a part of the organ, the overlying serosa being pale and smooth. The cut surface is light yellow, with gray interlacing strands. The larger tumors involve the muscularis, and in the cases of malignant carcinoid tumor, the serosa may be invaded, with the production of obstruction by kinking of the bowel. In the intestine there is a marked predilection for the terminal ileum, and in many instances multiple primary tumors are found. Metastases occur in about

25 per cent of the cases of intestinal carcinoids.

Since no characteristic clinical picture accompanies the presence of these tumors, the exact diagnosis is almost never made before operation is undertaken for what was considered to be chronic appendicitis or, in the case of the carcinoids of the small bowel, intestinal obstruction.

The treatment is resection, for all these tumors must be considered as malignant even though of a low degree. Recurrence of appendiceal carcinoids is rare, but this is not the case with those arising elsewhere in the intestinal tract. Here the chances of metastases are particularly great when the growth has reached relatively large size and has infiltrated all layers of the bowel wall.

WILLIAM DEW ANDRUS

THE AUTONOMIC NERVOUS SYSTEM

Surgery of the autonomic nervous system did not develop with the earlier knowledge of its anatomy, but with an understanding of the function of the craniosacral and thoracolumbar systems of nerves which has been built up by physiologists since the time of Claude Bernard.

The modern neurosurgeon stands particularly in debt to W. H. Gaskell and J. N. Langley of Cambridge University, to Francois-Franck of Paris and to Walter B. Cannon, professor emeritus of physiology at Harvard. He is especially indebted to the Cambridge physiologists for the knowledge of the finer arrangement of the autonomic nervous and also for the classification of these nerves into two opposing systems: the craniosacral or parasympathetic system on the one hand and the thoracolumbar or sympathetic system on the other. The latter leaves the spinal cord only between its first thoracic and second lumbar segments, while the former is given off from the brain stem and the sacral segments. The antagonistic action of these two divisions is most clearly expounded in Cannon's book on *The Wisdom of the Body*,¹ which every student who is interested in the subject should read. Cannon is chiefly responsible for the investigation of medullary-adrenal activity, as well as the discovery of sympathin, a second sympathomimetic hor-

more which is produced at the nerve endings on smooth muscle. The clinical significance of chemical mediators of autonomic nerve impulses is just beginning to appear and will

pathetic chains for the relief of angina pectoris.

Surgeons of the present generation have applied these fundamental physiologic prin-

INNERVATION OF Periph. Blood Vessels

INNERVATION OF VISCERA Sensory and Motor

Fig. 176.—The outgoing vasomotor and autonomic fibers to the extremities from the lateral horn of the spinal cord are illustrated diagrammatically on the left side. On the right side are shown the mixed motor (sympathetic) and sensory (posterior spinal root) fibers together with the principal visceral plexuses which they supply and the spinal segments from which they are derived. Preganglionic sympathetic axons are indicated by continuous lines and postganglionic by interrupted lines. The asterisk indicates the presence of pain fibers running to the posterior roots.

be discussed later. While Gaskell and Langley were investigating the motor activity of the visceral nerves, François Franck first conceived of their importance in pain and urged surgeons to remove the cervical sym-

pathetic chains for the relief of angina pectoris. Surgeons of the present generation have applied these fundamental physiologic prin-

pain. By regarding each case of sympathetomy as an experiment in human physiology, certain surgeons have contributed a practical understanding of the subject far beyond the limits of laboratory investigation.

The development of surgery of the autonomic nervous system has been so rapid that much of what was written in the previous editions of this book has had to be revised. Among the most valuable general volumes on the subject are Hovelacque's² superb textbook on neuroanatomy and Kuntz's³ monograph on the pathologic physiology of the autonomic nervous system. The most useful surgical monographs have been written by Gask and Ross,⁴ Livingston,⁵ and White and Smithwick.⁶ A still more recent description of operative methods has just been prepared by White for Pichler's new volume on neurosurgical operative technic.⁷

Clinical Methods of Study.—Accurate diagnostic tests have made it possible to determine in advance the effect of a proposed operation and to establish exactly which structures are to be resected. These tests depend on two fundamental principles: (1) inhibition of sympathetic activity by an appropriate stimulus such as raising the body temperature, to observe the degree of vasodilatation which results and (2) temporary paralysis of the sympathetic ganglia or their rami with procaine.

Body Heating Tests.—An effective method of abolishing vasoconstrictor tone is to raise the body temperature by enclosing the patient's trunk in an electrically heated cabinet with the hands or feet protruding into the cool air of the room (Lewis and Pickering).⁸ A still simpler way is to immerse the forearms or legs in hot water and to determine the vasodilator response which follows in the opposite exposed extremities (Laudis and Gilbon).

All of these tests depend on the fact that when the body needs to eliminate heat it does so in large part by radiation. Blood is shunted through the subcutaneous vascular bed particularly in the hands and feet. These vasomotor adjustments are mediated by the sympathetic nervous system but cannot take place in the presence of clattered peripheral arteries. The fundamental factor in the quantitative estimation of vasospasm of neurogenic origin is not the total rise in the temperature of a given digit which depends in large part on its initial temperature but on how nearly it approaches the normal vasodilatation level. Morton and Scott⁹ have proposed this term and placed its lower limit at approximately 87° F. (90° F. seems to be a little higher a safer figure). They have further suggested

terms of the occlusion index, i. e., the maximum surface temperature recorded subtracted from the normal vasodilatation level. In typical cases of Raynaud's disease the occlusion index is 0 whereas in arteriosclerosis the very slight vasodilator response falls far short of the normal level.

Diagnostic Nerve Block with Procaine.—A third type of test was proposed by White¹⁰ and by Morton and Scott.⁹ It consists of the temporary paralysis of the sympathetic nerves with procaine. This can be most easily accomplished by injecting the mixed peripheral nerves at their most accessible points, i. e., the posterior tibial nerve at the internal malleolus or the ulnar under the medial epicondyle at the elbow. Since the vasoconstrictor supply to the arteries is given off segmentally from the mixed nerves, complete vasodilatation

Fig. 177.—Spinal anesthesia test. The first patient, Edwin A., suffered from arterial occlusion due to thromboangiitis obliterans. In addition to this, there was a distinct element of vasospasm. Definite improvement followed lumbar ganglionectomy.

The response shown by the second patient, Robert M., is typical of excessive vasoconstrictor tone. This patient was relieved of all symptoms by lumbar ganglionectomy.

tion will develop in the anesthetic zone. In doubtful cases spinal anesthesia is the most certain method of inducing complete vasomotor paralysis in the legs (Fig. 177) and paravertebral injection of the uppermost thoracic sympathetic ganglia in the case of the upper extremities. For the investigation of obscure painful syndromes, such as causalgia, or unusual types of visceral pain paravertebral injection can give a selective block of the sympathetic pathways. From the response to these tests it becomes possible to select certain cases for treatment by alcohol injection or sympathectomy without recourse to the more mutilating procedures of cutting posterior roots or the spinothalamic pain pathways in the spinal cord. Procaine block constitutes the most accurate form of diagnostic test and should be used in all doubtful cases.

Treatment of Vasospasm of Neurogenic Origin—The arteries are far from being a set of rigid tubes but constantly vary their caliber for the maintenance of homeostasis. The autonomic nervous system constitutes the mechanism by which these changes are regulated. In certain pathologic states this autonomic adjustment is thrown out of balance and a chronic state of vasoconstriction or dilatation results. The former situation is seen in Raynaud's disease and acrocyanosis. It frequently plays a contributing role in thromboangitis obliterans and in post-trau-

digital arterioles while the pulsating vessels at the wrist and ankle usually maintain their normal volume. The color changes are one of the most striking signs of the disease. These consist of varying shades of cyanosis which are present most of the time. As the disease advances attacks of blanching digital asphyxia make their appearance on exposure to cold. This Raynaud's phenomenon is probably due to the onset of endarteritic changes in the digital arterioles.* The color pattern is extremely symmetrical (Figs 178 and 179). Usually all the fingers with the

Fig 18—Raynaud's disease. Note the dead white appearance of the fingers in the stage of digital asphyxia.

matic painful states of the extremities. In severe polyomyelitis it may be the cause of trophic ulceration. By far the most common and important of these conditions is Raynaud's disease.

Raynaud's Disease—This malady was first described by Maurice Raynaud¹⁰ in 1862; many excellent descriptions have followed, one of the best being that of A. W. Allen.¹¹

Raynaud's disease is a form of peripheral vascular disturbance caused by spasmodic contraction of the smaller arteries in the extremities. The vasospasm involves only the

possible exception of the thumbs are involved and most often the toes to a similar extent. In a sufficiently warm environment

*I can see no purpose in differentiating between classical Raynaud's disease described in this definition and such allied vasospastic conditions as acrocyanosis. In the former cyanosis alternates with pallid asphyxia while in the latter the extremities are constantly blue as well as abnormally cold. The palms and soles in addition to being cold and discolored are usually moist from excessive sympathetic stimulation of the sweat glands. Both conditions have a common underlying cause and both can be relieved surgically by cutting the vasoconstrictor pathway, provided secondary endarteritis or scleroderma has not complicated the picture.

the circulation becomes normal. Each case however has a critical thermal level below which the extremities react like those of a cold blooded animal and fall to room temperature. In the severe case recovery of normal circulation is slow and incomplete even in a warm room. As a result the patient lives in a constant state of discomfort and partial digital asphyxia. In the digital arteries which show no histologic changes in the early stages of the disease a form of obliterating endarteritis may develop. Painful ulcers slowly appear at the tips of the fingers and sclerodermatous changes develop

dicneephylon. On the other hand Sir Thomas Lewis¹² as a result of some extremely interesting observations has arrived at a diametrically opposite viewpoint. He maintains that the vasomotor tone is normal but that the peripheral vasospasm is due to an oversusceptibility to cold inherent in the smooth muscle of the digital arterioles. It is quite impossible in the brief space allotted to this subject to discuss this controversy here. Suffice it to say that everyone who has made a careful study of the advanced cases agrees with Lewis that the arteries eventually become definitely abnormal and that the dis-

Fig. 170.—Raynaud's disease. The left figure shows the stage of severe ulceration. There are also moderate sclerodermatous terminal scarring of the second and third fingers of the right hand and excessive perspiration.

in the skin. In the advanced cases terminal dry gangrene gradually leads to necrosis of the distal phalanges and a functionally useless hand. The disease is ten times more common in women than in men. It most frequently appears in the decade following puberty and is most often encountered in persons of a nervous emotionally unstable type.

The etiology of Raynaud's disease is unknown. Most authorities have felt that the peripheral vasospasm is due to an overactivity of the vasoconstrictor nerves possibly imposed by the autonomic centers in the

order cannot then be fully rectified by paralyzing the vasomotor nerves. Lewis' contention that the sympathetic nerves are not hyperactive is quite another matter—the commonly associated overactivity of the sweat glands is a strong argument against any such conclusion. From a long study of the early stages of the disease from the observation in three cases of a mild form changing into a severe one after emotional trauma and from the complete abolition of vasospasm in the feet after lumbar ganglionectomies (which Lewis has not taken into account) the writer cannot help but feel that the sym-

pathetic nervous system plays the predominant role in the causation of this disease.

In differentiating Raynaud's malady from other types of peripheral vascular disease special emphasis should be laid on the importance of symmetrical involvement and the persistence of the peripheral pulsations. Asymmetrical color changes or ulceration should arouse a suspicion of thromboangitis obliterans if present in young males and of arteriosclerosis in patients over fifty or in diabetics. In all cases the presence of cervical ribs which at times cause confusing vascular disturbances should be ruled out roentgenographically.

From the therapeutic angle there are no safe effective vasodilator drugs. In rare cases in which the basal metabolism is low thyroid extract should be tried and may be of value. Artificial fever induced by injections of foreign protein will occasionally cause early ulcerations to heal. The same can be said for periarterial sympathectomy.* Unfortunately the improvement from these procedures is usually short lived. Surgical intervention must be sufficiently radical to insure complete interruption of the vasoconstrictor fibers to the extremity. This requires an attack on the paravertebral chains of sympathetic ganglia which run along the anterolateral aspect of the thoracic and lumbar vertebrae.

Operative measures designed to interrupt vasoconstrictor tone must take into account the general physiologic principle that when ever sympathetic fibers degenerate the denervated smooth muscle is rendered hypersensitive to sympathomimetic hormones such as adrenin and sympathin. This phenomenon of sensitization may be so intense after the postganglionic fibers (the lower sympathetic neurons which run from the regional ganglia to the digital arterioles) have

been cut that little clinical improvement results. On the other hand when preganglionic fibers (the upper sympathetic neurons running from the lateral horn cells in the spinal cord to the paravertebral ganglia) are severed it is barely noticeable. It has been a common observation that the results of resection of the lumbar sympathetic trunk are uniformly satisfactory, whereas after the older form of cervicothoracic ganglionectomy the circulation in the hands although improved often remains inadequate. White, Okelberry and Whitelaw¹³ have pointed out that this divergent response to apparently similar procedures lies in the anatomical arrangement of the sympathetic fibers to the upper and lower extremities (Fig. 176). As the postganglionic neurons to the sciatic nerve originate in the lowest lumbar and upper sacral ganglia only the preganglionic neurons are divided by resecting the second and third lumbar ganglia. After cervicothoracic ganglionectomy on the other hand the entire postganglionic network to the arm degenerates and the vascular tree is rendered highly sensitive to circulating vasoconstrictor hormones.

To obviate this extreme degree of sensitization Smithwick^{6, 14} has devised a modified type of sympathectomy for the upper extremity. This consists of an approach through the resected central end of the third rib followed by extrapleural exposure and division of the paravertebral sympathetic trunk beneath its third thoracic ganglion. This interrupts all preganglionic vasoconstrictor fibers below this level (they originate from the second as far down as the ninth thoracic segment) but leaves intact a few which emerge over the second and third intercostal nerves. These are interrupted by resecting the central end of these structures. In so doing it is important to cut the nerves within the intervertebral foramina central to their bifurcation into anterior and posterior roots and preferably within the rachnoid. Only by so doing is it possible to divide all emerging preganglionic fibers with certainty as well as to prevent their extraordinary tendency to regenerate. Even after these precautions we have found cases in which nerve regeneration has taken place. To avoid this source of late failure Smithwick⁶ has advocated covering the first and second thoracic

*A great deal of controversy has arisen over this operation which has been advocated by Leriche. Extensive investigation has shown that while the nerve supply of the visceral arteries runs along their sheaths that of the peripheral vessels is given off in a segmental manner by the mixed somatic nerves. There is no sound physiology evidence to defend the view that denervation of a peripheral artery can specifically influence the volume of its vascular bed. Any operation however destroys a certain amount of tissue which in being absorbed produces a foreign protein reaction and thereby a generalized vasomotor response. This may be detected for a week to ten days.

ganglia freed up in the preceding steps of the operation by a sleeve of fine silk and burying the protected distal stump in the second intercostal muscle. In this way the decentralized cervicothoracic ganglia which give rise to the postganglionic neurons to the brachial vascular tree are preserved but are protected from the ingrowth of regenerating preganglionic fibers by a dense capsule of scar tissue.*

For the lower extremity the second and third lumbar ganglia should be resected. This can be carried out either transperitoneally through a midline incision which permits a bilateral resection at one stage or retroperitoneally through a modified renal incision. In either case the retroperitoneal space behind the cecum or sigmoid is entered and the lumbar chain is exposed in the gutter formed by the outer edge of the vena cava or aorta, the vertebrae and the psoas muscle. Under ordinary circumstances the extraperitoneal posterior incision is safer and preferable.

In experienced hands the risk from thoracic and lumbar ganglionectomy is remarkably slight. The chief essentials to justify such radical operations are accurate diagnosis and the demonstration by procaine injection or other diagnostic procedures that an adequate degree of vasodilatation will ensue. Under these circumstances thoroughly satisfactory and lasting improvement has followed resection of the second and third lumbar ganglia in a large series of patients with Raynaud's disease treated at the Massachusetts General Hospital. The permanent benefit in circulation of the hands has been far less satisfactory but is constantly improving. Replacement of cervicothoracic ganglionectomy by the preganglionic operation was the first important advance. The earlier patients submitted to this procedure had a most satisfactory circulation at first but a small number suffered recurrences at six to nine months from regeneration of vasoconstrictor activity. Since the adoption of the silk cylinder technique to prevent regenerating fibers from reaching the decentralized cervicothoracic ganglia regeneration has become an infrequent complication. Satisfactory results

may therefore be anticipated in the early and complicated cases of Raynaud's disease. With severe attacks of digital blanching and ischemia or in advanced scleroderma where endothritic changes have already occurred an adequate recovery of circulation cannot be expected.

Thromboangitis Obliterans (Buerger's Disease)—This disease although primarily due to arterial occlusion is frequently associated with and aggravated by vasoconstrictor spasm. By this mechanism the all-important collateral vascular bed is reduced. Improvement in circulation and relief of symptoms usually follow its release by lumbar sympathectomy even in cases in which no immediate improvement can be demonstrated by diagnostic procaine block. In the absence of actual gangrene but with a critically low pedal circulation or complicating intermittent claudication it has become the practice in the Peripheral Vascular Clinic at the Massachusetts General Hospital to perform a lumbar sympathetic ganglionectomy* in the younger group of patients if the femoral pulse has not been obliterated. A significant reduction in the number of major amputations has resulted. However in the presence of painful digital ulceration or incipient gangrene it is better first to crush the peripheral nerves above the ankle as advocated by Smithwick and White.¹³ This operation is far more efficient for relieving pain and can be counted on to cause maximal vasodilatation for a period of several weeks. If adequate collateral circulation fails to develop lumbar ganglionectomy can be carried out at a later date with the assurance of reproducing a corresponding degree of vasodilatation which will be permanent.

Postoperative Cold Extremities with Ulceration—In numerous patients with poliomyelitis as well as other types of spinal cord injury cold evanescic extremities with ulceration develop. These have responded well to sympathetic ganglionectomy provided the paralysis was not too great but in extremities in which all muscular activity has disap-

* There is no good evidence that any vessels retractor fibers to the upper extremity leave the spinal cord above the second thoracic nerve.

* To secure the maximal increase in circulation in the upper leg the first lumbar ganglion should be removed along with the second and third but if this is true on both sides the power of ejaculation will be lost as in the male patient rendered sterile but not impotent.

peared total elimination of vasoconstrictor tone is not likely to restore a normal circulation

Rheumatoid Arthritis—Great interest was aroused eighteen years ago by Rowntree and Adson's¹⁶ report that certain cases of polyarthritis with involvement primarily of the fingers, wrists and ankles and with accompanying vasospasm could be improved by sympathectomy and the restoration of a normal peripheral circulation. In the writer's hands two such cases have been most disappointing and few other clinics have corroborated the original enthusiastic reports.

Hyperhidrosis of Nervous Origin—Excessive perspiration limited to the palmar surfaces of the hands and feet is occasionally seen in young and nervous persons of either sex. While the condition is rare it may be extremely annoying and even incapacitating in certain occupations. This type of sweating may become so intense under nervous strain that beads of water drip from the fingers. As a result it becomes embarrassing to shake hands, papers are wet in handling and when rubber gloves are worn they become filled with sweat. The same condition may also involve the feet with the result that the socks and even the shoes are constantly wet through. Under these circumstances the skin becomes foul smelling, macerated and a prey to fungus infections. Psychotherapy, radiation or local applications fail to give relief but the results of sympathectomy are invariably satisfactory and frequently give dramatic psychic as well as local benefit.

Pain in Extremities Secondary to Vaso-spasm—Pain in the arms and legs after trauma and amputation is unfortunately an all too common complication especially after war wounds. This usually takes the form of cutaneous hyperesthesia to the scar or amputation stump or a deep aching or burning sensation which runs up the limb especially when it is cold. This condition is most commonly seen in individuals with cold cyanotic moist extremities and can usually be relieved by interruption of the underlying vasospastic state. The literature and a number of striking examples have recently been reviewed by White.¹⁷ It is evident that the pain is not transmitted by the sympathetic nervous system but is in some way related to the inadequate circulation.

Even temporary restoration of a normal blood flow by paravertebral procaine block of the regional sympathetic ganglia may clear it up especially if repeated on a number of occasions. When pain is relieved but recurs as the vasodilator response to procaine disappears thoracic or lumbar sympathectomy can be counted on to give lasting relief.

The Autonomic Nervous System and the Regulation of Blood Pressure—The regulation of blood pressure for the varying demands of the body with changes in external and internal environment is mediated by the autonomic nervous system. The central control lies in groups of cells situated in the medulla and diencephalon. Trauma, encephalitis and tumors which injure these areas occasionally produce profound changes in the vasomotor tone. An important peripheral mechanism for the reflex regulation of blood pressure and heart rate has been found by Heymans and his co-workers¹⁸ to lie in the aortic nerves and in the carotid sinus. The latter which has nervous connections with the vagus, the cervical sympathetic and the medulla through a branch of the ninth cranial nerve may become hypersensitive and produce an interesting clinical syndrome. Weiss and his associates¹⁹ have reported observations on 39 patients who suffered from spontaneous attacks of dizziness, weakness and unconsciousness with or without convulsions in whom mechanical stimulation over the bifurcation of one or the other carotid artery promptly induced an attack. Depending on the efferent pathway involved three forms of this carotid sinus syndrome are found: (a) cardioinhibitory, (b) vasodilator and (c) cerebral. The first type is due to a vagal reflex and can be abolished by atropine; the fall in arterial tension can be prevented by ephedrine but the cerebral variety can be treated only by denervation of the sinus. Numerous patients with spontaneous epileptic seizures induced by slight pressure on an irritable sinus have been relieved by operation.

The paroxysmal profound alterations in blood pressure which are caused by tumors of the adrenal medulla have been discussed in the preceding chapter. These are abolished by removal of the tumor.

A third and by far the most important

abnormality in the regulation of blood pressure is seen in essential hypertension. While the cause of this condition remains unknown it has now been established beyond any doubt that surgery has something to offer the hypertensive patient. Of suitably selected patients under fifty (and preferably under forty) who are free from permanent renal damage and who still have a labile blood pressure which falls with complete rest and sedation it is to be expected that a high percentage will have a persistent and significant lowering of blood pressure and relief from their symptoms after radical sympathectomy.* The proof that vasoconstrictor fibers to the lower half of the body have been interrupted is established when there is a profound fall in blood pressure as the patient stands. Under these circumstances regression of eye ground changes, decrease in the size of the heart, improvement in the electrocardiogram, increase in renal function and relief of symptoms are noted. Reports from many sources have demonstrated that the hands of the clock can be set back at least a number of years in the majority of younger hypertensive patients but sufficient time has not yet elapsed to determine the exact increase in life expectancy.

The most reasonable explanation for the decrease of arterial pressure which follows sympathectomy in hypertensive subjects is the general reduction in tone of smooth muscle in the denervated vascular bed and the elimination of neurovascular reflexes which occur in the viscera, muscles and skin in response to psychic stimulation and homeostatic adjustments. In general the lowering of blood pressure observed has been directly proportional to the extent of the sympathectomy and inversely proportional to the severity of the disease. The operations in current use vary considerably in their extent. They fall into three main groups: (a) supradiaphragmatic ganglionectomy and

splanchnicectomy as employed by Peet and his colleagues; (b) the subdiaphragmatic operation of Allen and Adson¹ and (c) the combined more radical thoracolumbar denervation of Smithwick. Both of the first two procedures are open to the objection that they do not completely denervate the lower half of the body and it is furthermore very unlikely that the limited length of splanchnic fibers that can be removed from beneath the diaphragm is sufficient to prevent regeneration. In the postoperative results reported by Peet in 51 per cent of the patients a satisfactory reduction in blood pressure developed in Adson's case a similar improvement is reported in less than 40 per cent. In the hands of other surgeons results after the less complete operations have not been impressive.

The combined thoracolumbar approach of Smithwick² permits the removal of a great length of the splanchnic trunks as well as of the ganglionated chains from the ninth thoracic down through the first or second lumbar segments. Provided the splanchnic resection is complete to the level of the seventh or eighth ribs and the sympathetic trunk is removed in a point below the second lumbar* ganglion sympathetic vasoconstrictor impulses to the abdominal viscera as well as to the muscles and skin below the umbilicus should be abolished (fig. 176). A most significant point is that before adopting this somewhat more extensive procedure Smithwick² had tried the more limited operations above and below the diaphragm. His results in these were not as satisfactory as those recorded in the reports of their advocates but with the adoption of the combined operation in 1938 a significant improvement took place. In his last statistics Smithwick² has summarized the results in 156 hypertensive patients studied for a period of one to five years. These he divides into five groups on the basis of the postoperative fall in diastolic pressure. In 61.5 per cent of the entire series comprising groups 1 and 2 the diastolic pressure fell

* Although the above constitute the most rigid requirements for insuring a satisfactory reduction in blood pressure, Smithwick (personal communication) has had a large percentage of successful results in patients in the upper forties and even over fifty as well as in others whose blood pressure failed to fall on sedation. Some of his very best results have been obtained in spite of very high apparently fixed diastolic pressures which did not respond to either rest or sedation.

* It is important to point out that if the sympathetic chains are resected bilaterally below the level of the first lumbar ganglion the male patient will be sterilized. While potency and the sensation of orgasm are not lost, viable spermatozoa can no longer be ejaculated.

over 20 mm with an average reduction of 61 mm systolic in two thirds and 43 mm diastolic in the remaining one third. In group 3 in which the reduction in blood pressure was probably also significant there was an average reduction of $\frac{27}{15}$ mm. This group constitutes an additional 18 per cent of the total. In groups 4 and 5 which contain the remaining one fifth of the series there was no significant change. The mortality rate amounted to 2.8 per cent. Favorable changes in eye grounds, electrocardiograms and renal function together with an improvement in the well being of the patient suggest that lowering of the blood pressure sets up a gen-

erally to the terminal visceral plexuses without synapses in the ganglia. It is therefore best to think of them as displaced somatic fibers and to call them the visceral afferent nerves. Studies of the conduction of pain from the internal organs have demonstrated two main types of afferent conduction.

1. Referred pain of the type described by Head¹ and Mckenzie.² This theory assumes that visceral afferent impulses run only as far as the posterior horn of the spinal cord. It is further postulated that impulses reaching this region from a diseased organ set up an irritable focus and thereby reduce the sensory threshold to stimuli from the surface of the body. As a result the constant bombardment of afferent impulses from the

TABLE 4—SENSORY INNervations OF THE VISCERA

Organ	Superficial areas to which pain is referred	Visceral ram which carries pain
Heart	Precordium and inner arm	T ₁ T ₃ or T ₄
Lung	No evidence of pain until parietal pleura and intercostal nerves are involved	
Esophagus	Substernal distress	T ₅ -T ₆ *

eral improvement and a reversal of the degenerative vascular changes which take place in hypertension. How long the present five year cures are to last still remains uncertain.

Sympathectomy for the Control of Visceral Pain.—The classic conception of the autonomic nervous system is that its pre-ganglionic and postganglionic neurons are purely the regulators of visceral activity. In the earlier studies little attention was paid to larger myelinated nerve fibers which originate from cells in the posterior root ganglia. These cells send dendrites to the posterior horn of gray matter in the spinal cord and axons through the sympathetic plexuses to the internal organs. These axons run di-

rectly to the terminal visceral plexuses with out synapses in the ganglia. It is therefore best to think of them as displaced somatic fibers and to call them the visceral afferent nerves. Studies of the conduction of pain from the internal organs have demonstrated two main types of afferent conduction.

2. Direct transmission of visceral pain. Over fifty years ago Ross³ wrote that in addition to sharp well localized referred pain a diseased organ might also cause a deep all defined sense of discomfort. He called the

skin which normally fail to reach the level of consciousness become magnified into painful sensation. This type of pain is sharp it is not necessarily localized over the organ in question but is often referred to such a distant area as the medial side of the hand in angina pectoris. This occurs because some of the cardiac ram enter the spinal cord at the same level as the plantar nerve. Weiss and Davis have shown that pain of this sort is abolished by infiltrating the cutaneous area of reference with novocain.

latter "splanchnic" or "direct" visceral pain. This important contribution was lost sight of in later years, but there is good evidence that visceral pain may reach the thalamus without any referred cutaneous mechanism, because it can be evoked in animals and in human beings after all cutaneous afferent impulses have been interrupted. This direct type of sensory conduction presumably transmits the dull aching form of visceral pain which is vaguely localized to the region of the diseased organ.

inal viscera over the vagus nerves, but this is an important pathway for pain transmission from the upper part of the trachea and esophagus.

From a knowledge of these mechanisms it is obvious that pure visceral pain can be interrupted by destroying either the regional sympathetic ganglia or their rami. Section of the posterior spinal roots or the contralateral spinothalamic tract (cordotomy) will also produce a loss of visceral sensation. The two latter procedures, however, because of

Fig 180—The sympathetic cardiac nerves. Diagram showing why cervical sympathectomy often fails to relieve pain from the heart. The operation does not interrupt the recently discovered thoracic cardiac nerves. These carry sensory impulses from the posterior cardiac plexus directly to the upper thoracic ganglia. It is questionable whether a connection from the fourth thoracic ganglion ever exists. From clinical evidence this must be very rare. Destruction of the upper three thoracic ganglia or the upper four pairs of posterior spinal roots results in complete sensory denervation.

Whenever an inflammatory or neoplastic process spreads from a viscus to the neighboring parietal pleura or peritoneum, the intercostal nerves become the chief pathway for conduction of pain, e. g. in pleurisy, appendicitis or cholecystitis with local peritoneal involvement. This is also the case in carcinoma of the lung and is the reason why sympathectomy usually fails to give relief.

No form of pain is known to reach the sensorium from the heart, lungs or abdom-

inal viscera over the vagus nerves, but this is an important pathway for pain transmission from the upper part of the trachea and esophagus.

From a knowledge of these mechanisms it is obvious that pure visceral pain can be interrupted by destroying either the regional sympathetic ganglia or their rami. Section of the posterior spinal roots or the contralateral spinothalamic tract (cordotomy) will also produce a loss of visceral sensation. The two latter procedures, however, because of

can be resected surgically or destroyed by alcohol injection. The method of treating cardiac pain by paravertebral alcohol injection has been described by White.²⁶ It is by far the safest method of treating pain in

Fig 181—Paravertebral injection in angina pectoris. The photograph shows points of injection under the lower borders of the upper five ribs and the zone of cutaneous anesthesia. This patient has had complete relief from anginal attacks in the left side of the chest and in the arm for over six years.

cases of angina pectoris or aortic aneurysm, but accurate injection is technically difficult to achieve in about 10 per cent of cases. Furthermore, in a small number of patients the alcohol sets up an irritating neuritis, which may last for a number of weeks. The advantages of injection therapy for the patient who is a poor risk so far outweigh the disadvantages that it is the writer's present routine to use this method for patients with advanced cardioaortic disease. If it fails to give sufficient relief, posterior root section or cordotomy may be undertaken later. For the patient with angina pectoris who is a fair surgical risk, resection of the upper three thoracic sympathetic ganglia is the ideal surgical procedure. In the case of cardiac pain the work of White, Garrey and Atkins²⁷ has shown that the recently discovered direct thoracic cardiac nerves, which connect the upper thoracic sympathetic ganglia with the heart, account for the frequent failures of the older operation of cervical sympathectomy.

(Fig. 180). When these ganglia or the upper five posterior thoracic spinal roots are destroyed, sensation from the heart is consistently interrupted. In my first case of angina pectoris treated by alcohol injection, complete relief of left-sided pain lasted for over six years (Figs. 181 and 182).

A good understanding of the value of this form of neurosurgical treatment for the relief of intractable pain may be obtained from table 5, which summarizes the cases in which treatment was given at the Massachusetts General Hospital. While the results of sympathetic denervation are most dramatic in the relief of otherwise intractable cases of angina pectoris, this method is proving to be equally valuable in the treatment of numerous other forms of visceral pain seen in idiopathic dysmenorrhea, aneurysm of the aorta, nephralgia, etc., which are listed in table 5. For further details of the applications and technic of sympathectomy for visceral pain the reader is referred to the monograph of White and Smithwick.²

Some of these patients were operated upon by Drs W J Miller, J V Meigs and R. H. Smithwick and are included in this series with the permission of these surgeons.

* "Good" results include only those patients who obtained from 100 to 90 per cent relief, "improved," from 90 to 40 per cent relief.

† One patient with an excellent early result had a partial recurrence of angina pectoris in the subclavicular region. It could not be determined whether this was due to removal of only three ganglia or through transmission over nerves on the right side.

‡ There have been three other deaths in this series which do not seem to be justly attributable to the procedure. A nonburnt woman of 80 was given injection treatment on account of the unbearable nature of the cardiac pain and died of bronchopneumonia. In an old asthmatic patient, severe bronchial asthma developed 11 or 12 weeks after injection and caused fatal pneumonia. A third patient, a man of 56 with rheumatic fever, aortic regurgitation and the most severe form of anginal attacks, died of progressive cardiac decompensation ten days after an injection, which had relieved his pain.

CERVICAL RIB

Cervical ribs (Fig 185) in man are anomalous structures rather than examples of evolutionary reversion Jones attributed the embryological formation of supernumerary ribs to a conflict between forming plexuses and ribs

The snake being without neck waist arms or legs possesses two ribs for each vertebra with corresponding separate segmental nerves In high forms the limb buds cover several vertebral segments the nerves from which grow into the buds The diametric growth of the limb buds however does not keep pace with the longitudinal growth of the vertebral column and segmental nerves soon have to pursue an oblique course to enter the buds Then begins the conflict between the obliquely running nerves and the newly forming ribs The embryonic nerve trunks in the embryo are far larger in proportion to the vertebrae and ribs than in the fully developed animal The obliquely running nerves normally impede the growth of the ribs to the extent that they merely form vertebral processes Todd

the transverse process (2) more advanced the rib reaching beyond the transverse process either with a free end or touching the first rib (3) almost complete the rib connecting with the cartilage of the first rib and (4) complete the rib becoming possessed of a true cartilage that unites with the cartilage of the first rib In several cases I have observed prominent and enlarged transverse processes on the seventh cervical vertebra which produced symptoms similar to those observed in the syndrome of cervical rib

Symptoms—The pain may be sharp and lancinating or it may be a dull ache It usually follows the distribution of the nerves leaving the lower part of the trunk at the brachial plexus but occasionally it may ex-

Fig 185—Roentgenographic appearance of cervical ribs

tend upward to the shoulder and into the neck The pain may be more or less continuous and it is invariably exaggerated by rotation of the head or by a forceful downward pull of the shoulder If a patient has been told that he has cervical ribs he will probably complain of vague pains and of general discomfort about the neck and shoulder which can hardly be attributed to the existence of short cervical ribs The patient with cervical ribs that actually produce symptoms usually gives the history of pain following any sudden or violent exertion Housewives usually complain of radiating pain following sweeping washing or dusting One woman complained of pain and numbness along the distribution of the ulnar nerve following difficult labor at childbirth A physician complained of severe pain which was

Vesical distention of neurogenic origin unfortunately is not amenable to treatment by sympathectomy. Dennis Brown¹² and others have shown that there is a crude form of reflex bladder emptying mediated by the intrinsic plexuses of the vesical wall so that the paralyzed bladder can partially empty itself in the absence of its extrinsic nerves. When the innervation of the bladder is intact stretch reflexes are mediated over the sacral parasympathetic fibers and lower centers in the sacral cord. The hypothalamus and premotor cortex exercise an inhibiting control on vesical contraction. The normal act of urination is mediated by parasympathetic fibers derived from the second, third and fourth sacral nerves. The sympathetic fibers which come down through the superior hypogastric plexus carry motor impulses which affect the passage of spermatozoa down the vas deferens and the act of ejaculation but their destruction causes little if any change in vesical function. It can be detected in the cystometrogram. As a result of these recent investigations and the unsatisfactory results following operation the older theory that the function of an overdistended "cord bladder" could be improved by presacral neurectomy has been discarded.

In this short review of surgery of the autonomic nervous system no attempt has been made to discuss the treatment of diseases in which recent experience has found sympathectomy to be of little practical value. These include exophthalmic goiter, epilepsy, and spastic paralysis. It is interesting, however

Vesical distention of neurogenic origin unfortunately is not amenable to treatment by sympathectomy. Denny-Brown²⁸ and others have shown that there is a crude form of reflex bladder emptying mediated by the intrinsic plexuses of the vesical wall, so that the paralyzed bladder can partially empty itself in the absence of its extrinsic nerves. When the innervation of the bladder is intact, stretch reflexes are mediated over the sacral parasympathetic fibers and lower centers in the sacral cord. The hypothalamus and premotor cortex exercise an inhibiting control on vesical contraction. The normal act of urination is mediated by parasympathetic fibers derived from the second, third and fourth sacral nerves. The sympathetic fibers, which come down through the superior hypogastric plexus, carry motor impulses which affect the passage of spermatozoa down the vasa deferentia and the act of ejaculation, but their destruction causes little, if any, change in vesical function that can be detected in the cystometrogram. As a result of these recent investigations and the unsatisfactory results following operation, the older theory that the function of an overdistended "cord bladder" could be improved by presacral neurectomy has been discredited.

In this short review of surgery of the autonomic nervous system, no attempt has been made to discuss the treatment of diseases in which recent experience has found sympathectomy to be of little practical value. These include exophthalmic goiter, epilepsy, and spastic paralysis. It is interesting, however, to recall that cervical and lumbar rhizotomy, proposed by Royle and Hunter for the reduction of muscle tone, although not generally accepted for the treatment of this particular condition, led directly to the present operations for Raynaud's disease and megacolon. With the possible exception of the much discussed subject of hypertension, experience with sympathetic neurosurgery in the conditions taken up in this chapter has now reached a point where the effects of these operations are well known and their therapeutic value in properly selected cases is thoroughly established.

CERVICAL RIB

Cervical ribs (Fig 185) in man are anomalous structures rather than examples of evolutionary reversion Jones attributed the embryological formation of supernumerary ribs to a conflict between forming plexuses and ribs

The snake being without neck waist arms or legs possesses two ribs for each vertebra with corresponding separate segmental nerves In high forms the limb bud is covered several vertebral segments the nerves from which grow into the buds The lamellar growth of the limb buds however does not keep pace with the longitudinal growth of the vertebral column and segmental nerves soon have to pursue an oblique course to enter the buds Then begins the conflict between the obliquely running nerves and the newly forming ribs The embryonic nerve trunks in the embryo are far larger in proportion to the vertebrae and ribs than in the fully developed animal The obliquely running nerves normally impede the growth of the ribs to the extent that they merely form vertebral processes Todd stated that in the fetus, ribs are normally present in articulation with vertebrae above the eighth and that after birth they are present only as transverse processes of the cervical vertebrae

Gruber divided cervical ribs into four groups according to the extent of growth (1) slight degree the rib reaching beyond

the transverse process (2) more advanced the rib reaching beyond the transverse process either with a free end or touching the first rib (3) almost complete the rib connecting with the cartilage of the first rib and (4) complete the rib becoming possessed of a true cartilage that unites with the cartilage of the first rib In several cases I have observed prominent and enlarged transverse processes on the seventh cervical vertebra which produced symptoms similar to those observed in the syndrome of cervical rib

Symptoms—The pain may be sharp and lancinating or it may be a dull ache It usually follows the distribution of the nerves leaving the lower part of the trunk at the brachial plexus but occasionally it may ex-

Fig 185—Roentgenographic appearance of cervical rib

tend upward to the shoulder and into the neck The pain may be more or less continuous and it is invariably exaggerated by rotation of the head or by a forceful downward pull of the shoulder If a patient has been told that he has cervical ribs he will probably complain of vague pains and of general discomfort about the neck and shoulder which can hardly be attributed to the existence of short cervical ribs The patient with cervical ribs that actually produce symptoms usually gives the history of pain following any sudden or violent exertion Howelives usually complains of radiating pain following sweeping washing or dusting One woman complained of pain and numbness along the distribution of the ulnar nerve following difficult labor at childbirth A physician complained of severe pain which was

projected along the median and ulnar nerves after struggling with an insane patient who attempted to commit suicide. Hyperesthesia, paresthesia and anesthesia may be associated with the pains and may persist after strenuous exertion. Decreased reflexes and loss of motor power do occur when the symptoms are pronounced and of long duration. Patients with mild symptoms do not require operation unless the blood pressure and radial pulse can be reduced or stopped by elevation of the chin and rotation of the head to the affected side on inspiration. Atrophy occurs late and is rarely complete.

In 1903 Thorburn reported 2 cases of atrophy of the ulnar nerve muscles of the hand associated with cervical rib. Jones in a series of 14 cases of atrophy of the ulnar nerve muscles of the hand on roentgenologic examination found cervical ribs present in 10. Wilson found atrophy to be of two types, the median or partial ulnar type and the ulnar type. In the former there is paralysis of the abductor pollicis muscle and the opponens pollicis muscle which are supplied from the sixth and seventh cervical nerves; the remaining ulnar muscles are intact. The flexor pollicis longus is also supplied by the median nerve but probably from a different segment. The ulnar type *man en griffe* in which there may be paralysis of all the muscles of the hand except the two innervated by the median nerve is the result of injury of the eighth cervical nerve.

Circulatory symptoms are rarely severe. One arm or hand sometimes becomes more deeply cyanotic than the opposite upper extremity, with mild trophic changes in the tips of the fingers. Several cases have been reported however in which gangrene of one or more fingers occurred. In this event obliteration of either the radial or the ulnar artery or of both also usually occurs. Diminution in the volume of the radial pulse is frequently observed on the affected side. This phenomenon can be accentuated by instructing the patient who has cervical rib to sit upright on the examining table with the arms relaxed to take a full breath to elevate the chin and then to rotate the head to the affected side. The diminution in the radial pulse is due to compression of the subclavian artery between the scalenus anticus muscle and the brachial plexus which has been displaced forward by the supernumerary rib. Unless the symptom is associated with other complaints little or no relief will be obtained by removal of the cervical rib or section of the scalenus anticus muscle.

The presence of Horner's syndrome has been attributed to traction on the stellate sympathetic ganglion. In one of the cases in the writer's series the patient complained of a reflex cough every ten or fifteen seconds; this was relieved by sectioning an anomalous twig from the phrenic nerve which had been caught in the scar tissue where the scalenus anticus muscle compressed the subclavian artery. The brachial symptoms were relieved by tenotomy of the scalenus anticus muscle.

Surgical Considerations.—In a review of cases observed at the Mayo Clinic it was learned that the incidence of cervical ribs was 0.056 per cent. Of 303 patients with cervical ribs 84 were males and 219 females. Roentgenographic examination revealed by lateral cervical ribs in 143 cases, a unilateral rib on the right in 70 and a unilateral rib on the left in 60, a supernumerary cervical tubercle was invariably present on the opposite side in all cases of unilateral cervical rib. In 167 cases (55 per cent) the presence of cervical ribs was discovered accidentally by means of roentgenograms as there were no symptoms. In 81 cases the roentgenograms were positive but since the symptoms were mild and indefinite in character operation was not advised. In 57 cases the symptoms justified surgical treatment.

The older surgical procedures consisted of resecting supernumerary ribs by the lateral or posterior approach. The writer followed this method until he had occasion to explore through the supraclavicular triangle the subclavian artery of a patient with cervical ribs who complained of the classic syndrome and who had gangrene of two fingertips. He then observed that removal of the rib only partially relieved the pressure and it was not until the tendinous insertion of the scalenus anticus muscle was divided at the first rib that all constriction about the subclavian artery and the brachial plexus was relieved (Fig. 186).

Prior to 1923 23 patients had been operated on by the transcervical or posterior approach for the removal of cervical ribs. Since then the writer has operated on 10 patients through the anterior cervical approach at which time the tendinous insertion of the scalenus anticus muscle was divided in conjunction with removal of the

cervical rib The anterior cervical approach has continued in use but division of the tendinous insertion of the scalenus anticus muscle is the only procedure employed. This same surgical procedure is employed for the relief of the *scalenus anticus syndrome* a group of symptoms simulating those produced by a cervical rib. However they have arisen from an enlarged transverse process on the seventh cervical vertebra and narrowing of the space between the process and the posterior border of the scalenus anticus muscle. In comparing the

arterial occlusion have developed. In 2 cases cervicothoracic sympathetic ganglionectomy was performed subsequently to relieve vasospastic phenomena. There has been only 1 death in the series and that was of a patient who had gangrene of the index and middle fingers, thrombosis of the radial artery and a large elbow like atheromatous change of the subclavian artery under the scalenus anticus muscle. This patient's immediate convalescence was uneventful but on the twentieth postoperative day the calcareous plaque gave way and the patient

Fig. 186.—Diagrammatic representation of compression of the subclavian artery and brachial plexus between the cervical rib and the scalenus anticus muscle and of the relief of compression on section of the muscle at its insertion.

results of the various operations it was observed that this newer procedure was more effective than mere removal of the cervical rib and that the results were equally as good as the results obtained when the rib was removed in conjunction with division of the tendinous insertion. Radiating pain and paresthesia are quickly relieved by the operation unless there is marked evidence of irritation of the nerve root and atrophy of muscles. The circulatory phenomena improve and disappear unless permanent changes such as atheromatous patches and

died from hemorrhage before the subclavian artery could be ligated proximal to the point of rupture.

Surgical Technique.—An oblique incision is made for a distance of about 5 cm. extending upward and backward from the sternoclavicular articulation into the posterior triangle. The incision is carried through the platysma myodes muscle and fat until the tendon of the sternocleidomastoid muscle with its attachment to the clavicle is exposed. The clavicular attachment is divided between two forceps. The muscle portion is then reflected medially, exposing the tendon of the omohyoid and the tendinous attachment of the scalenus anticus muscle with the phrenic nerve running

obliquely across it from the lateral to the caudal border. During dissection the transverse cervical and the suprascapular arteries are divided and ligated. The scalenus anticus muscle is dissected free and the phrenic nerve is retracted medially before the tendinous and muscular insertion is divided. The subclavian artery will appear on the lateral side of the scalenus anticus muscle and if the space between the cervical rib (or the cervical rib and the tendinous bands to the thoracic rib) and the lateral border of the scalenus anticus muscle is narrow one immediately observes compression of the subclavian artery against the trunk of the brachial plexus. On the mesial side of the scalenus anticus muscle one may observe the pleura and if dissection is carried still farther medially the carotid sheath and the vertebral artery will be exposed this however is unnecessary.

It is important to carry the dissection upward on the anterior surface of the scalenus anticus muscle for a distance of 5 cm in order to expose the phrenic nerve thoroughly before retracting it medially. One must bear in mind before dividing the scalenus anticus muscle at its insertion that it lies over the compressed portion of the subclavian artery and that the pleura is situated medially to the inner border of the muscle in order to avoid injury to both structures. Section of the musculotendinous insertion is most easily accomplished by dividing the fibers in small groups with scissors. The cut fibers promptly retract upward thus exposing the undivided fibers and the compression of the artery. As soon as the scalenus anticus muscle has been divided the subclavian artery will be seen to slide forward and take on its normal caliber and the lower trunk of the brachial plexus will likewise slide forward and downward to be free in the supraclavicular triangle.

The wound is closed in much the same manner as any operative wound. The scalenus anticus muscle retracts upward. If division of the omohyoid tendon has been necessary it should be reunited by suture before the clavicular portion of the sternocleidomastoid muscle is resutured with inattress sutures of chromic catgut. The patient may be permitted to sit up on the day following operation. He may be dismissed from the hospital in three days and from the surgeon's care as soon as the wound in the skin has healed.

Comparing the technique of the anterior approach and division of the scalenus anticus muscle with the lateral approach and retraction of the brachial plexus necessaries to expose and resect the cervical rib one appreciates very readily the difference between the two methods to say nothing of the relative effectiveness of the two procedures. The former can be carried out with ease and without danger of traumatizing the brachial plexus whereas the latter requires considerable dissection and retraction of the brachial plexus.

BIRTH PALSIES

The term birth palsy should be confined to cases in which the evidence justifies the assumption that the fetus was intact at the beginning of labor and was damaged by some one of the various stresses incident to delivery.

The difficulties in diagnosis are formidable partly because of the obvious fact that stresses and their effects are so difficult to appraise and partly because it is so hard to discuss "birth injury," "obstetrical accident" and so on without some implication of obstetrical mismanagement. Obviously very little progress will be made if the diagnosis is involved with a controversy of this sort.

The reasonable attitude is to start with the idea that the process of labor involves severe stress on the nervous system of the child and that the obstetrician fulfils his duty when he does his best to control all the various forces. The occurrence of injury, whether from rupture of tissue, edema, asphyxia or anoxemia, implies that the obstetrician was not able to prevent an imposition of stresses which were beyond the child's limit of tolerance, but it most emphatically does not indicate any ignorance or lack of skill on the part of the obstetrician.

With this understanding it is profitable to attempt to understand the forces which affect the nervous system of the child.

The brain the spinal cord or the peripheral nerves can be injured. In a brief review it is impossible to consider the various controversial matters but in general the discussion can be separated into three divisions.

Cerebral Palsies—Definition—Any motor disturbance due to injury of the brain is a result of parturition. In general certain postnatal conditions such as bleeding due to hemorrhagic disease of the newborn are usually included since a differential diagnosis is essentially impossible.

Etiology—1 Rupture of tissue particularly rupture of the intracranial septa with consequent disturbances of pressure relations and bleeding from the veins and sinuses which are enclosed between the layers.

2 Edema due to prolonged or excessive pressure particularly when early rupture of the amniotic membranes leads to gross differences in pressure on the part of the head occupying the os uteri and the rest of the fetus.

3 Intracerebral or intraventricular hemorrhage without rupture of the dural septa.

4 Hemorrhage due to constitutional causes or to asphyxia as such.

5 Anoxemia due to occlusion of the placental circulation by strangulation of the cord or premature separation of the placenta.

On the whole the mechanical factors are most readily understood and are most easily studied from a prophylactic standpoint. In general premature infants are peculiarly liable to intracranial hemorrhage regardless of the method of delivery. Obviously dystocia increases the liability to injury and without question in a very large proportion of breech deliveries the infant suffers from trauma. Forceps used skillfully and with restraint probably play a less important part than is usually stated.

Diagnosis in the period immediately after birth depends on two things. First on evidence that no prenatal lesion can account for the condition second on evidence that the brain is not functioning in an adequate manner. Prolonged apnea after birth recurrent cyanosis refusal to nurse or convulsions are the usual symptoms. On examination changes in the reflexes bulging of the fon-

tanelle and apathy or irritability with irregular respiration are frequent.

Lumbar puncture frequently reveals important evidence but neither a high cerebral spinal fluid pressure nor blood in the fluid is pathognomonic. Direct puncture through the suture line below the angle of the fontanelle is often advisable in order to establish the presence of subdural or ventricular bleeding.

Later in infancy or in childhood the diagnosis is less certain and is made by establishing the presence of a cerebral lesion and reviewing the history of the labor and of the neonatal period. Encephalography is often of great value. Also it is obvious enough that any cerebral injury severe enough to produce motor signs may involve sensory and mental mechanisms. Any appraisal therefore should include a careful study of the effect of the supposed lesion on the intellect of the child.

Prophylaxis depends on the obstetrician and on his ability to modify the stresses on the fetus.

Surgical treatment in the immediate postnatal period is concerned largely with the control of hemorrhage and with the control of intracranial pressure. Transfusion after suitable study of the blood and injection of whole blood are the methods of control of hemorrhage. The role of vitamin K is still somewhat confused. Undoubtedly hemorrhagic disease of the newborn can be largely prevented but it is doubtful whether vitamin K is useful in the treatment of established intracranial hemorrhage. The best summary was presented in a round table discussion published in the *Journal of Pediatrics* in 1949. Rigid attention to quiet practically like that given premature babies is needed. Probably more injured babies die from too much manipulation and exposure than from too little surgical intervention. In some cases repeated punctures or even direct surgical attack on a subdural hematoma is worth trying. In recent years the subject has received increasing attention and a paper by Ingraham and Matson summarize the present situation adequately.

Later on the advisability of palliative surgical treatment depends on a careful and conservative appraisal of the remaining physiologic assets. Operations of any kind

ire of course futile in the presence of gross feeble-mindedness and should be reluctantly undertaken unless there is clear evidence that reasonable intelligence exists

The confusion about types of operation would be enormously diminished if a careful psychologic and physiologic appraisal preceded discussion of indications

Spinal Birth Palsies—The care in the writer's experience always the result of direct force imposed on the child by the obstetrician. Usually they result from breech extraction. As far as I know they are never helped by direct surgical attack on the lesion itself. Later treatment depends on the degree of damage which varies from almost complete disintegration of the whole lower cord to trifling damage to the anterior horn cells.

Birth Palsies of the Brachial Plexus—Palsies of this sort are relatively common. The essential mechanism in most cases is lateral traction on the head against a shoulder which is still within the birth canal. The injury is frequently confined to the upper roots of the plexus but may involve the whole plexus and the sympathetic fibers connected with it.

Surgical exploration of the plexus is legitimate but it is wise to postpone it until it is clear that recovery without operation is unlikely. While waiting a period of from several months to a year the prevention of contractures is essential. Carefully planned splints usually ones which maintain the arm in abduction and external rotation or carefully supervised physiotherapeutic routines or combinations of the two are necessary. In later cases in which deformity occurs as a result of contractures and bony changes in the shoulder joint corrective operations of the type suggested by Sever are of great value.

SPINA BIFIDA AND CRANIUM BIFIDUM

(*Meningocele Myelomeningocele Encephalomeningocele*)

Definition—Hernial protrusion of the meninges through vertebral or cranial defects occurs in infants as a congenital abnormality. The hernial sac contains cerebrospinal fluid and often nervous tissue is present free in the sac or attached to its walls.

Types of Spina Bifida and Cranium Bifidum—A large number of classifications have been proposed hence the complexity of nomenclature is confusing. From the surgical standpoint the following simplification and alteration of the classification used long ago by von Recklinghausen is practical.

Spina Bifida with Meningocele—Meningocele is associated with a local unfinished closure of the vertebral arch or arches. The overlying skin may be normal or covered by a thin parchment-like epithelium. The sac is composed of the meninges and contains only spinal fluid.

Spina Bifida with Myelomeningocele—Nerve roots or the spinal cord may be present in the sac or attached to its walls. In myelomeningocele there are many different degrees of involvement of the spinal cord but it seems unnecessary to marshal the bewildering number of names which have been applied to the various forms of these anomalies.

Rachischisis is a term used arbitrarily in this instance to designate the more extreme abnormalities encountered in cases of spina bifida. The bony defect is wide because of the absence of laminae and pedicles and nervous tissue is directly exposed. There is little or no sac formation. The defect is both menoblastic and epiblastic.

Spina Bifida Occulta Posterior (or Anterior) with Meningocele—The overlying skin is normal in appearance except for frequent hypertrichosis or a lipomatous mass beneath it. The defect is usually posterior but sometimes protrusions take place through a defect in the vertebral bodies and the sac projects into the abdominal cavity or the thorax.

Spina Bifida Occulta Posterior (or Anterior) with Myelomeningocele

Cranium Bifidum with Meningocele—These hernial protrusions occur almost invariably at the midline. They are usually dorsal and are found most commonly in the occipital region but sometimes are ventral, extending into the mouth.

Cranium Bifidum with Encephalomeningocele—As in myelomeningocele the amount of nervous tissue in the sac is variable.

Cranioschisis—As in rachischisis the nervous tissue is exposed and there is little or no sac.

are to be seen in great numbers throughout the tissue. There are usually many irregular clumps of cells with large nuclei. These cellular clumps which are often in intimate contact with the blood vessels resemble closely the arachnoidal cell nests with which one is familiar in the fully developed arachnoid. Such clumps often connect the fluid spaces within the tissue with vessels, thus resembling the arachnoidal collections in the pachyonian granulations or arachnoid villi. There are also other similarities. In sacs removed from adult patients numerous psammoma bodies have been identified and chromatophore cells identical in appearance with those seen normally in the leptomeninges have been encountered. Finally it has been demonstrated that the tissue spaces in the sac communicate with the subarachnoid space. If lampblack is injected into the

Fig. 187—Schematic horizontal section illustrating cases of spina bifida. A, Sacral meningocele; B, sacral myelomeningocele; C, high lumbar myelomeningocele. Note that the sac is continuous with the dura mater and is separable from the skin.

The Meningocele, Myelomeningocele and Encephalomeningocele Sacs—In the meningocele, myelomeningocele and encephalomeningocele there is a fluid-containing sac beneath the skin or its parchment-like continuation. The dural and arachnoidal membranes are usually inseparable at the mouth of the cranial or spinal defect, and the sac is an outward continuation of this undifferentiated meninx (Fig. 187). Nerve roots or the spinal cord itself may be attached to or incorporated in the sac in spina bifida, and there may be similar attachments in cranium bifidum in the encephalomeningocele. The meningocele sac is always separable from the skin, though separation is difficult when the skin covering is thin and parchment-like.

Histologically the sac is composed of loose collagenous tissue resembling arachnoid. Thin-walled veins

cisterna magna soon after death the spaces in the sac are filled with it, and the ink stops abruptly at the point where sac tissue passes over into the surrounding connective tissue.

Therefore it is evident that there is a cellular differentiation within the sac of meningocele, *et al.* which strikingly resembles the arachnoidal membrane and that the arachnoidal cell clusters bear the same relationship to blood vessels and cerebrospinal fluid spaces in the sac as they do in arachnoid villi and pachyonian granulations. From the histologic evidence it would seem that there is absorption of cerebrospinal fluid into the blood stream within the sac.

Embryological Considerations—General—In the normal human fetus the entire neural tube closes at about the end of the third week of intrauterine life. Mesoblastic tissue grows between the surface ectoderm and the neuroectoderm and from this tissue develop the membranes which are to enclose the central nervous system, the vertebrae and the skull. At about the eleventh week the vertebral canal from the first cervical to the third or fourth sacral vertebra is covered over by the union of the laminae. The spinal cord and vertebral column are of equal length until the twelfth

week. As the fetus grows the vertebral canal becomes proportionately longer until the conus is left at the level of the twelfth thoracic or first lumbar vertebra in adult man. It is obvious therefore that developmental anomalies on which these abnormalities are based make their appearance at an early embryological period. If nerve roots or the spinal cord are involved the upward migration of the cord is prevented. This is a factor which must be considered when symptoms develop later in life in patients with spina bifida but which is of no significance in the problems presented by cranium bifidum.

The Experimental Production of Spina Bifida and Anencephaly—One of the most conclusive chapters in experimental teratology is the subject of spina bifida. Hertwig in 1892 described the development of spina bifida in frog embryos which he thought was due to polyspermy. He was able to produce the anomaly only occasionally by his experimental method. Nevertheless drawing from von Recklinghausen's exhaustive article on human spina bifida, Hertwig pointed out that his own experimental findings might indicate the true mechanism by which spina bifida is produced. In 1902 Morgan and Tsuda found that if frog's eggs were placed in a 0.6 per cent solution of sodium chloride the blastophore did not close and spina bifida resulted regularly, producing also some specimens showing typical anencephaly. With this more reliable experimental method Hertwig continued his studies and extended the observations to other species. As a result of his work Hertwig finally questions whether it is not possible for chemical substances in the blood to pass from the human uterus to the ovum in order to produce these abnormalities. He concluded that these abnormalities could be produced in any embryo by altering its normal environment. The fact that malformations occur in embryos artificially incubated has long been recognized by embryologists.

Etiology of Spina Bifida Suggested by the Study of Pathologic Human Embryos—Mall collected many human embryos and encountered various types of cranium bifidum and spina bifida among them. He was able to demonstrate pathologic changes in the chorion in most of the embryos showing abnormality. This was usually the result of an endometritis which prevented proper implantation. The embryos from tubal pregnancies showed a much higher percentage of malformations than those from the uterus. A point Mall emphasized to bring out the significance of faulty implantation. His specimens showed not only an arrest of development but also tissue destruction and scar formation. At the stage of closure of the neural tube the nervous tissue is very sensitive and the period is a critical one. Mall showed that when the effect of faulty implantation is operative at this time the deformity results and that if the embryo is to continue to grow the placental abnormality must correct itself.

Mall concluded as had Hertwig that spina bifida and cranium bifidum are due to the action of external influences on the egg after fertilization. The principal significance of the observations made from experimental embryology and from aborted human embryos is their bearing on the question as to whether the defects are inherited or acquired. These observations favor the viewpoint that they are acquired. If Mall's conclusions

are accepted then any woman who has had a pathologic embryo or a congenitally abnormal child should undergo gynecological examination and perhaps curettage before subsequent pregnancies are permitted.

The Cerebrospinal Fluid and Spina Bifida and Cranium Bifidum—The developmental anomalies in the neural tube leading to spina bifida and cranium bifidum take place long before cerebrospinal fluid is formed. Weeda's embryological studies have proved that cerebrospinal fluid is formed from the chorionic plexuses and from his work it is obvious that they develop and begin to function at a stage later than any which can affect the closure of the neural tube. He showed that with the passage of cerebrospinal fluid out of the ventricle into the un differentiated perimedullary mesenchyme spaces develop and the subarachnoid space is formed. The first passage of fluid out of the ventricle takes place normally through the roof of the fourth ventricle, and the first arachnoid differentiation takes place in the adjacent mesenchyme at this level. Weeda also demonstrated that the absorption of cerebrospinal fluid takes place through arachnoid villi, i. e. arachnoid cell nests which project into veins.

It seems justifiable to conclude that defects of the neural tube leading to spina bifida and cranium bifidum permit the early passage of ventricular fluid into the perimedullary mesenchyme at the level of the defect, which causes the early differentiation of the arachnoid at this level. There are formed not only spaces but arachnoid villi. It is our belief that arachnoid tissue of the meningeal sac provides for so much absorption of cerebrospinal fluid that there may be an necessity for the normal subarachnoid system to develop when a meningeal sac is present.

This hypothesis is strengthened by clinical evidence. When it was a customary surgical procedure to amputate meningeal sacs hydrocephalus frequently developed after operation. Cutler concluded that "while modern surgery has made amputation of the sac safe from meningitis it may be justly accused of causing death by hydrocephalus." He concluded as had others that there was clinical evidence that the sac was a safety valve for excessive cerebrospinal fluid but he failed to recognize the true functional significance of the sac. It was Penfield who first realized that the sac is an absorbing mechanism and that removal causes hydrocephalus because absorption of cerebrospinal fluid cannot keep pace with its formation when the absorbing tissues are taken away. Since operations have been carried out in which the meningeal sacs are dissected out and all the arachnoid tissue is preserved hydrocephalus has not developed postoperatively.

Associated Anomalies.—Multiple congenital anomalies associated but unrelated are sometimes encountered in the central nervous system with spina bifida and cranium bifidum. Two varieties of spina bifida may be present in the same case (Fig. 191 b). The writer has also encountered a simple meningeal sac with cranium bifidum and a sacral type of spina bifida in the same infant.

Hydrocephalus (Fig. 189, b) is a commonly associated congenital abnormality. However congenitally dilated lateral ventricles with a normal sized choroid plexus (Fig. 189, a) and other abnormalities are also commonly associated owing

perhaps to the same etiological factor but otherwise unrelated.

One of the important anomalies in spina bifida with myelomeningocele from the clinical standpoint is that related to the development of the protrusion with its enclosed nervous tissue. In myelomeningocele the spinal cord is fixed and cannot migrate upward during the disproportionate increase in the growth of the vertebral canal. Keiller's schematic drawings (Fig 189) illustrate the anomaly which results. This point deserves emphasis because the relationship of the cord to its surroundings is maintained as an embryonic relationship is present at the time of the origin of the defect. Traction on the attached cord may therefore be a factor in the etiology of symptoms occurring in later life (childhood, adolescence or adult life).

Types of Lesion—Keiller found reports in the literature of 170 cases of spina bifida in which she considered the anatomical data were accurate enough to permit of classification. After the cases were grouped to fit the classification which she proposed the percentages obtained were as follows: 41 per cent spina bifida occulta with symptoms, 2.3 per cent meningoceles with adherent crura equina, 70.6 per cent myelomeningoceles, 1.7 per cent arachnoid myelomeningoceles and 24.1 per cent simple meningoceles. The cases of simple meningoceles were the only ones in the series which did not present secondary nervous lesions, thus indicating that in 78 per cent of the cases there was incoherence of the cord or its nerve roots to some extent.

It is unfortunate for statistical purposes that a standard classification of types has not been accepted.

Fig 189—Meningoceles with associated malformations: *a*, Lumbar spina bifida with myelomeningocele and non-paralytic clubfeet; *b*, lumbosacral spina bifida with myelomeningocele and hydrocephalus.

Statistics—Frequency—Statistics are difficult to collect on the incidence of cranium bifidum. Spina bifida with protrusion is said to occur once in one thousand births, and in most large series of deliveries these figures are approximated. Keiller points out that the cases of spina bifida occulta not discoverable at birth are omitted in these figures.

Location—Moore's collected series of 385 cases treated by excision of the sac is one of the largest series reported from which statistics as to location are available. Since the patients were suitable for operation his series of course represents an already selected group of cases. Of the 385 cases, 23 per cent were sacral, 34 per cent lumbar, 29 per cent lumbosacral, 4.5 per cent thoracic, 9.5 per cent cervical. There were two patients with occipital meningoceles.

Symptoms and Signs—The presenting symptom in cranium bifidum with meningocele and encephalomeningocele is a protruding hernial sac situated in the midline of the skull. The protrusions are encountered at almost any point, though they are rarely related to the fontanelles. When the sac projects through the base, the nasopharynx may be obstructed, and there is usually an associated anomaly in the superior maxilla with cleft palate and sometimes harelip. Figure 190 shows some of the locations in which cranium bifidum with protrusion occurs.

In spina bifida with meningocele or myelomeningocele the protrusion is also in the midline and may be encountered at any level of the vertebral canal (Fig. 181). Only the occult variety offers any difficulty in immediate diagnosis.

The occult cases are relatively infrequent and do not require emergency treatment. The surgical problem presented is chiefly

meter of the overlying skin and the size of the bony defect through which they occur. Often the surface epithelium is irregularly lacking at birth, and cerebrospinal fluid percolates through the spongy tissue of the sac, keeping the surface moist. Again, the surface ectodermal covering may be complete, but the sac is so thin as to require the greatest caution during examination and nursing care

Fig. 189.—Diagrammatic representation of the migration of the spinal cord and the relation of the nerve roots *a*, in a three months' fetus, *b*, in a fetus at term, *c*, in myelomeningocele. The skeletal basis of all the figures was taken from the dissection of the spinal column of a seven months' fetus (Keiller)

one of fixation of the cord leading to traction on nerve roots and is different from that presented by spina bifida with posterior protrusion. In cases showing the rachi-chitic or cranioschitic type of anomaly with the spinal cord or brain exposed and little or no sac present, surgical treatment can accomplish little.

Examination of the Protrusion—(a) The protrusions vary greatly as to size, the char-

acter of the overlying skin and the size of the bony defect through which they occur. Often the surface epithelium is irregularly lacking at birth, and cerebrospinal fluid percolates through the spongy tissue of the sac, keeping the surface moist. Again, the surface ectodermal covering may be complete, but the sac is so thin as to require the greatest caution during examination and nursing care

(b) Transillumination of the protrusion in a dark room provides a simple procedure which aids in differentiating between the meningoceles containing only fluid and those containing nerve tissue. The projecting cere-

bral tissue can be outlined in cases of cranial defects and the nerve roots of the spinal cord itself can be identified running up to the sac in cases of spina bifida.

(c) Oxygen injected into the sac makes a ray visualization of the contents of the sac possible and also the outlines of the bony defect are clearly seen. Unfavorable reactions do not follow the use of this diagnostic procedure if suitable precautions are taken. The infant's head should be kept low in spina bifida and high in cranium bifidum. A long needle is inserted through normal skin

(d) Aspiration of the fluid from the sac and palpation when it is collapsed will give information as to the contents of the sac and the size of the bony defect. The same precautions that have been outlined to prevent subsequent leakage of cerebrospinal fluid are necessary. In addition to this and in order to minimize the effect of the sudden reduction of pressure in this diagnostic procedure the head should be kept low during and for a considerable period after the removal of fluid in cases in which the protrusion is below the level of the fourth ventricle.

Fig. 190—Location of meningoceles. *a* Into the mouth through a cranium bifidum at the base of the skull. *b* frontal cranium bifidum with meningocele. *c* posterior parietal cranium bifidum with small meningocele. *d* occipital cranium bifidum with encephalomeningocele. The nervous tissue was connected with both cerebral hemispheres.

at a considerable distance from the sac this prevents subsequent leakage of fluid. Fluid is removed in small amounts and replaced with like amounts of oxygen; the exchange being carried out until no more fluid can be removed. Plates are taken with the infant's head lower than the defect in cases of spinal defects with the head up in cases of cranial defects. Additional information may later be obtained by roentgenograms of the rest of the central nervous system if the position is gently altered so that oxygen may pass slowly from the sac to the subarachnoid space and the ventricles.

and conversely kept elevated when it is above this level.

(e) Electrical stimulation with weak faradic current in cases of spinal defects provides a further method of determining whether or not nerve roots or spinal cord tissue is present in the sac. As the electrode is drawn over the sac isolated motor responses will result as nerve roots are crossed and grouped muscle responses will be observed when the spinal cord is stimulated. Very young infants do not seem to resent this procedure and in older infants it seems to cause no more discomfort than the usual

sensory examination. In no instance in our experience have responses been observed following stimulation of the encephalomeningoceles

(f) Examination of the sac for ballottement by the application of sudden pressure over the fontanelle may give some indication of the freedom with which the sac communicates with the ventricular system and the subarachnoid space. An impulse can frequently be felt over the fontanelle when sudden pressure is made over the sac further indicating the freedom of communication.

Rachischisis and cranioschisis have not been considered with the foregoing because

the degree of involvement of the central nervous system, the direct result of the disease. Grave associated anomalies are usually fairly obvious and are not difficult to recognize. Incipient or early hydrocephalus is suggested by large fontanelles and open suture lines even before enlargement of the head has begun and the typical signs have developed.

Reflex and other motor activities in newborn infants differ from those of the adult. In a careful study Chaney and McGraw point out the responses to be expected in apparently normal infants immediately after birth and during the period they are kept in the maternity nursery. By a systematic ex-

Fig. 191.—a, Cervical spina bifida with meningocele, b, dorsal spina bifida with simple meningocele and lumbar spina bifida with myelomeningocele, c, lumbar spina bifida with myelomeningocele, d, sacral spina bifida with meningocele

they present little or no sac and nervous tissue is exposed. Because these deformities are routinely associated with other anomalies in the central nervous system, no surgical intervention is justifiable. Cases of cranioschisis have been reported in which the exposed brain has been stimulated electrically, and responses have been observed. In rachischisis, stimulations of the exposed cord by the lightest touch with cotton wool or with weak electrical currents often produce motor movements, showing that even this tissue, almost unrecognizable as spinal cord tissue, is capable of producing reactions.

General Examination.—A searching examination is carried out to determine the possible presence of other anomalies and

amination along the lines they indicate, information as to the presence of other associated defects of the central nervous system, as well as those secondary to the lesion, can be obtained.

Treatment.—*Surgical Treatment.*—For the last eleven years we have preserved the meningocele sac at operation in all cases of spina bifida and cranium bifidum with protrusion because of its absorbing function. Figures 192, 193 and 194 illustrate the steps in the surgical procedures in these conditions.

Under light ether anesthesia the infant is placed in the prone position with the meningocele uppermost and the body on a plane to minimize the escape of cerebrospinal fluid

After being shaved the skin is washed well with soap and water and sterilized with a 7 per cent solution of iodine left in place for three minutes before removal with alcohol. When ulcerated areas are present they are kept covered with dressings sutured to the skin.

from the sac until the neck of the sac is freely exposed passing into the defect of the vertebral column or of the skull. The sac is then opened widely enough to allow inspection of its contents, care being taken not to injure the nerve roots or spinal cord which may be attached. Nerve roots or the film

Fig 199—Plastic repair of cranium bifidum with encephalomeningocele. 1 and 2 Dissection of the skin from the sac. 3 opening made into the sac and exposure of the cerebellum and cisternal plexus. 4 the formation of a fascial tent over the collapsed sac with fascia lata obtained from the infant's father. 5 horizontal section of the repair.

A circular incision is carried around the body of the protrusion so as to preserve as much good skin as possible. The skin above the incision is peeled off to the apex by sharp dissection. Even a parchment like covering will come off intact like a transparent hood if sufficient care and patience are exerted. The skin below the incision is then reflected

terminale should be dissected free from the sac if this can be done without injury to them. Otherwise nervous elements and even spinal cord should be left attached to the sac. Electrical exploration with weak faradic and galvanic currents aids greatly in the identification of nervous tissue which is capable of responding and is always carried out

efore the cystic cavities which are present in the spinal cord are opened and drained, it is to be certain that the incision will pass through functionless tissue.

When the sac of the meningocele contains cavity, as it usually does, the fluid is evacuated and the incision is then closed with interrupted sutures. If the sac contains only puggy tissue with small loculi, fluid will escape from it when it is cut across, and it is treated in the same manner. The collapsed

In some cases the sac itself has a dense capsule near its base, and if it is rolled over on itself, the uppermost wall of the sac proper will serve as a tent if the edges are fastened to the deep fascia by interrupted sutures. A further fascial layer may or may not be sutured over this. Buried sutures are then taken to approximate the skin edges so that the skin can be sutured without tension. The skin closure requires ingenuity at times if the protrusion is large

Fig 103—Plastic repair of spina bifida with lumbosacral myelomeningocele. A, Schematic representation of findings at operation before relationships were disturbed and also the beginning dissection of skin from the sac; B, the sac is collapsed and covered with a cotton pad to protect it during retraction. The nerve roots leaving the involved segments of the cord and passing to the intervertebral foramina through tissue of the sac are shown; C, schematic representation of the plastic repair. The sac is covered by a fascial tent made by reflecting and suturing fascia from the lumbar muscles over it. With the collapse of the sac, the nerve roots lie in folds and cannot be stretched as they were when the sac was distended with cerebrospinal fluid.

and closed sac is rolled up or placed in a heap. It is impossible to get it all into the spinal canal or cranial cavity. Instead, it is left *in situ*, and a fascial tent is made over it.

The tent of protective fascia may be secured from the fascia lata of the father's thigh. In most cases, however, the sac is too great in volume to be covered by flaps of deep fascia which carpets the adjacent bone and muscle of the infant. These flaps are cut and turned over the sac, the attachment to the bony defect being preserved,

and covered partially by parchment-like epithelium. Great care must be given to hemostasis to prevent hematoma. We usually institute drainage for twenty-four hours through a stab wound and use silk sutures throughout.

It is perhaps unnecessary to point out that all measures which aid in preventing shock should be employed in operating on young infants. Control of hemorrhage and prevention of chilling are two of the most important rules to be observed.

Postoperative Treatment—The infant should be moved to its bed without changes in position that is prone and with head down in the case of spinal protrusion in order to prevent loss of cerebrospinal fluid. Feedings are resumed as soon as the baby will nurse. Until the wound is healed the child is kept prone, the feet being tied in position if necessary. This prevents soiling and keeps the dressing dry.

After the wound is healed the head of the infant's crib is kept elevated. If the fontanelle pressure is high the parents are instructed to aid the absorption of fluid by postural and dehydration treatment as follows. The head of the crib is raised as much

Selection of Cases for Operation—In all cases of simple meningoceles and uncomplicated myelomeningoceles surgical treatment should certainly be carried out. The decision for or against operation in cases in which there are associated defects and complications must remain largely a matter of individual opinion. The associated anomaly hydrocephalus has led us to advise against surgical intervention as have the related or secondary complications which are extreme: a complete paralysis of the sphincters and complete paralysis of the extremities. We have been gratified in many of the cases of myelomeningocele by the improvement in signs following operation. While damage

Fig. 194.—Plastic repair of lumbosacral myelomeningocele. Flaps from the deep fascia are being used to cover the collapsed but intact sac.

as possible. When the infant is carried it is kept erect, never horizontal. With the advice of a pediatricist the fluid intake is reduced to a minimum and the diet is changed to a solid one very early, although the bowels may become constipated as the result of fluid restriction. We have used these procedures for the past twelve years and have found them most helpful in the treatment of borderline cases of hydrocephalus when the absorption of fluid is only a little less than the formation of fluid. As a postoperative precaution it not only serves to reduce intracranial venous pressure, thus promoting the absorption of fluid, but it raises the pressure in the spinal sac and probably promotes escape there.

Already done cannot be repaired, relief of tension due to traction on the cord or nerve roots by the bulging sac must account for this improvement. Some of the little patients thus operated on may never be able to join the joyous crowd at the piper's back, but can nevertheless live happily and usefully.

Optimum Time for Operation—Plastic repair of meningoceles, encephalomeningoceles and myelomeningoceles should be carried out at the end of the third or fourth week of life when conditions are optimum. At this time the mother can come to the hospital. The supply of breast milk is well established and the dangers of hemorrhage and sepsis are much less marked than in

the newly born. If the sac is so thin that rupture is imminent and repeated punctures are contraindicated earlier operation is advisable. When the sac is ulcerated or has already ruptured at birth operation is carried out at once. When a patient is seen late and ulceration is present it is necessary to wait until complete epithelization is well established before attempting the procedure; otherwise meningitis is almost inevitable. During the waiting period the tension in the sac may be kept down by repeated aspiration, a needle being inserted through normal skin of the back well to the side of the defect. A doughnut made of cotton wool will protect the sac from trauma if nursing care is sufficiently expert.

The time of operation is a much disputed question. Many surgeons prefer to wait nine or ten months, meanwhile carrying out successive punctures; some advise waiting until the child is five years of age. Frazier states that 80 per cent of the untreated patients die during the first year. Plastic repair carried out early saves many of these lives.

Discussion.—Many years ago John Hilton pointed out the dangers of the methods of treatment of the disease called spina bifida then current. He warned the students of Guy's Hospital in 1863 against the use of the knife and found it safer to tap and bandage the protruding cystic sac than to inject or ligate it. The present knowledge of the relationship of the cysts of the sac to the subarachnoid space makes one shudder at the practice of injecting iodine into these protrusions.

The development of aseptic technique has prevented in large measure the postoperative meningitis of Hilton's time, but the reports in the literature since its adoption are still discouraging. The failures which have followed the procedure of amputation even in the most expert hands are due to the fact that in a large percentage of cases the amputated sac has an important, sometimes indispensable function to serve. Moore estimated that the operative mortality was 50 per cent in the series of case reports that he collected. Craig, describing the attitude at the Mayo Clinic, also gives the operative mortality of 50 per cent if amputation is carried out at an early age. Cutler's figures were nearly 60 per cent.

The operation we have described provides for the preservation of the sac beneath a protective tent of fascia so that it can continue to absorb cerebrospinal fluid. Operation therefore does not increase the likelihood of the development of hydrocephalus as it does when the sac is amputated, and hydrocephalus has not developed postoperatively in our cases. The operative mortality has been reduced to 14 per cent in spite of the fact that it is our custom to operate at the end of the third week of life or not once if the sac is ulcerated or ruptured. Postmortem studies have shown the presence of associated anomalies except when death resulted from infection, indicating that surgical treatment was ill advised in these instances.

A point which can be raised in criticism of the surgical technique as we are carrying it out in the Neurosurgical Clinic of the Montreal Neurological Institute concerns the method of treating the spinal cord tissue which is adherent to the sac in cases of myelomeningocele. Thus far it has been a theoretical point, although our longest follow up is but twelve years. We have never excised nervous tissue in the cases of spina bifida even though it was so redundant that it could not be returned to the vertebral canal. In spite of Keiller's conclusion as a result of anatomical studies that attached cord usually shows no tissue which is capable of functioning and should therefore be removed at operation we have so frequently obtained responses when it was stimulated electrically that we have not dared to remove it. It is possible that in some of our cases signs due to fixation of the cord may yet develop as they have in some occult cases, and further surgical attempts to free these may be necessary. The problem of fixation of the cord, however, can be left to the ingenuity of the neurosurgeon. It is not an immediately urgent problem like that of the protruding meningocele.*

HYDROCEPHALUS

General Description—The typical picture of hydrocephalus is seen in the infantile cases in which the head is huge and heavy. The increased pressure of the cerebrospinal fluid in the greatly dilated ventricles has forced the yielding skull with its open fontanelles and sutures to expand, producing the grotesque head with the large calvarium

and overhanging forehead above the greatly stretched upper eyelids and a normal-sized face, which appears small by contrast (Fig 195). This condition in infants is commonly caused by malformations or developmental errors and is termed *congenital hydrocephalus*. Hydrocephalus which develops in adolescence or adult life is usually the result of a brain tumor and is termed *acquired hydrocephalus*. In these cases the head is not enlarged, as the skull has become a firm bony box after the closure of the sutures, and the pressure of the cerebrospinal fluid results only in the enlargement of the ventricles by compression of the brain tissue against the skull.

The accumulation of the cerebrospinal fluid may be rapid or slow. In some instances a balance may be established with no further accumulation of fluid, and the hydrocephalus is thus arrested. If, however, the aggregation of fluid began in infancy the large head persists.

Types of Hydrocephalus.—*Obstructive, Internal or Non-Communicating*—The dilatation of the ventricular system may be due to a block somewhere in its course so that the cerebrospinal fluid, which is formed by the choroid plexus of the lateral ventricles, is unable to escape into its absorbing channels. This obstructive or non-communicating type of hydrocephalus is unilateral if the block occurs in the region of one foramen of Monro. Bilateral enlargement of the lateral ventricles would be produced if the obstruction occurred (1) at both foramina of Monro, (2) or in the third ventricle, (3) or in the aqueduct of Sylvius, (4) or in the fourth ventricle or (5) at the midline foramen of Magendie and the lateral foramina of Luschka of the fourth ventricle (Fig. 196).

Communicating, External.—Communicating or external hydrocephalus produces the same dilatation of the ventricular system as occurs in the non-communicating type, but the blockage is found in the absorbing spaces for the cerebrospinal fluid. The absorbing channels consist of large lakes or cisterns along the base of the brain between the pia mater and pia arachnoid which communicate with the subarachnoid spaces over the surface of the cerebral and cerebellar lobes and the spinal cord.

Etiology.—In the non-communicating or obstructive type of hydrocephalus the block in the ventricular system may be due to (1) malformations of the brain, such as atresia or absence of the foramina, of the aqueduct of Sylvius, or of a cerebral hemisphere, diaphragms or vascular bars in the aqueduct or third or fourth ventricle, (2) malformation of the skull distorting the brain stem and obstructing the aqueduct or cisternae, as in achondroplasia, (3) strictures resulting from inflammatory conditions or (4) tumors (cystic, vascular or solid) in the midline structures; septum pellucidum,

stricture and prevent absorption of the cerebro-spinal fluid. Tumors in the leptomeninges, such as medulloblastoma, endotheliomatosis or gliomatosis of the meninges, that seed themselves throughout the subarachnoid channels may produce moderate grades of hydrocephalus by interfering with the absorption of the cerebro-spinal fluid.

Symptoms and Signs.—In infants, because of the yielding of the skull and subsequent enlargement of the head, few or no signs and symptoms of increased intracranial pressure may be manifest. Usually there is a retardation in mental development, but it

Fig. 105.—An extreme case of hydrocephalus. This boy, aged three years, had an almost normal mentality.*

corpus callosum, suprasellar region, pineal region, midbrain, pons, cerebellar lobes and vermis.

In communicating hydrocephalus the cisternal and subarachnoid channels may be occluded owing to an inflammatory process or arachnoiditis, which produces scarring and adhesions in the meninges. The meningitis may be the acute type from bacterial invasion of the streptococcus, pneumococcus, meningococcus, etc., or it may be the subacute or chronic type seen in tuberculous, syphilitic and mycotic infections. Hemorrhages in the cisternal and subarachnoid cerebral spaces may lead to fibrosis and

is surprising the extensive compression of the cerebral tissue that may take place without causing appreciable mental changes.

When the skull is unyielding, after the closure of the fontanelles and sutures, and forms a bony box with only one opening (the foramen magnum), hydrocephalus will produce the symptoms of general increased intracranial pressure. These are (1) headaches, generalized or occipital, (2) vomiting, which frequently occurs without nausea or relation to meals and is often forceful so that it has been termed projectile, and (3)

* Dandy in Lewis: *Practice of Surgery*. W. F. Prior Co., Publisher.

failing vision. Double vision, usually due to weakness of the sixth nerve, may be present but is of no localizing value.

Signs of increased pressure appear as irritability or drowsiness, slowed pulse and respiration, increase in the blood pressure, edema of the optic nerve heads (called papilledema or choked disk) with at times exudate or hemorrhages in the retina as seen by ophthalmoscopic examination. A high-pitched percussion note or cracked-pot sound, Macewen's sign, indicates a thinning of the skull due to internal pressure. This is

sure, the cracked-pot sound on percussion of the head and convolutional atrophy of the skull.

The diagnosis, however, cannot be made with certainty from these findings since any space-occupying lesion within the skull, such as tumor, hemorrhage, cyst, subdural hematoma or hydroma, may develop without the production of hydrocephalus and give the same symptoms and signs both in infants and in adults.

A definite diagnosis of hydrocephalus can be made by Dandy's method of ventricu-

Fig 196—General plan of the cerebrospinal fluid system. The only exits by which the ventricular fluid may reach its absorbing bed in the subarachnoid spaces are through the paired foramina of Luschka and the median foramen of Magendie.*

confirmed by the convolutional atrophy seen in the roentgenogram (Fig 197).

Diagnosis.—Hydrocephalus in the infant is recognized by the enlargement of the skull, the peculiar appearance of the eyes caused by the stretching of the upper lids, the bulging fontanelles and separated sutures, varying grades of mental and physical retardation and the symptoms of increased intracranial pressure, if they are present.

Hydrocephalus in the child or adult will present one or all of the symptoms and signs of generalized increased intracranial pres-

sure. This consists of withdrawing ventricular fluid by means of a needle, introduced into the lateral ventricle either through a trephine opening in the skull or through an open fontanelle or suture and replacing this fluid by air. Roentgenograms taken after this procedure will outline the ventricles. A normal ventricle contains from 10 to 15 cc. of fluid. A capacity greater than 30 or 40 cc for both lateral ventricles is indicative of hydrocephalus (Fig. 198). Any abnormal change in the shape, size or position of the parts of the system.

* Dandy. Bull. Johns Hopkins

will be apparent in the ventriculogram and is of value in localizing the site of the cerebrospinal fluid block which is producing the hydrocephalus. For instance, failure to visualize the third ventricle completely or partly would indicate an obstruction in this region or a dilatation of the third ventricle along with that of the lateral ventricles would locate the obstruction in or posterior to the aqueduct of Sylvius.

Röntgenograms after the replacement of the cisternal and subarachnoid fluid by air (Dandy's encephalography) may be obtained to determine obstructive areas in the absorbing system. The injection of air is made through a needle introduced into the cisterna magna (cisternal puncture) or into the spinal subarachnoid space by spinal puncture. There is a real hazard in the spinal injection of air unless the increased intracranial pressure has first been reduced by removal of some of the ventricular fluid, otherwise lowering the pressure of the spinal fluid may cause a herniation of the tips of the cerebellar lobes into

The Dandy and Blackfan phenol-sulfonephthalein test may be utilized in making this differential diagnosis. Neutral phenol-sulfonephthalein, when introduced into the spinal subarachnoid spaces, diffuses upward

Fig. 129.—Ventriculograms, lateral and anteroposterior, showing the huge dilatation of the ventricles in hydrocephalus.

so that from twenty to thirty minutes after 1 cc. has been injected in the absence of obstruction in the ventricular system the dye can be detected in the aspirated ventricular fluid by its pink color after the addition of a few drops of sodium or ammonium hydroxide. All specimens of urine are saved for the first two hours and tested quantitatively for the dye. Normally the yield from the spinal subarachnoid space is less than 10 per cent, and for the combined cerebral and spinal subarachnoid channels it is between 30 and 40 per cent. A yield of from 10 to 20 per cent, therefore, would indicate a severe grade of communicating hydrocephalus.

This test provides the most satisfactory

Fig. 127.—Röntgenogram showing the convoluted atrophy of the skull of a youth with communicating hydrocephalus.

the foramen magnum which will compress the medulla and lead to respiratory failure.

Although hydrocephalus can be definitely diagnosed by ventriculograms, this procedure may not afford a differentiation between the non communicating and communicating types especially in infants.

method of differentiation between the more common obstructive type and the rarer communicating type of hydrocephalus in infants and children and permits the selection of appropriate therapeutic measures.

Treatment—Non communicating hydrocephalus in the youth or adult is usually produced by a tumor and is relieved by its removal.

The arrest or cure of hydrocephalus in infancy has interested physicians for centuries. Instances of spontaneous arrest are not uncommon and there are records of cases in which the frequent withdrawals of cerebrospinal fluid and a limitation of the general fluid intake stopped the progression of the accumulating fluid. But too frequently the rapid development of fluid and the progressive enlargement of the head call for surgical intervention.

Surgical treatment for the obstructive type of hydrocephalus has varied from the drainage of the ventricle into the subcutaneous or subdural spaces or into the blood stream by means of tubes or segments of vessels or by holes punctured through the corpus callosum into the ventricles to the establishment of a new aqueduct of Sylvius by the tube method or a new outlet made in the posterior velum when the obstruction is at the foramina of Luschka and Magendie. If the ventriculograms fail to show the localized area of the block and the phenolsulfonaphthalein test indicates the presence of normal absorbing channels several satisfactory procedures are available.

One method attempts to establish a free communication between the floor of the third ventricle and the underlying cisterna and interpeduncularis (Dandy's third ventriculostomy).

Another operation consists of removal of the choroid plexuses of the lateral ventricles either by resection or by their destruction with the electrocoagulating current. This choroidectomy will markedly diminish the formation of cerebrospinal fluid.

Treatment of the communicating type of hydrocephalus when exploration has revealed that it is due to multiple tumors in the meninges as in medulloblastomas may be cured for a time at least by applying deep roentgen therapy to the entire brain and spinal cord. A more common cause of com-

municating hydrocephalus is the sealing off of the cisternal and subarachnoid cerebral spaces by a chronic arachnoiditis which develops as a distressing sequel of meningitis. It is impossible to reopen these channels surgically; hence removal of the choroid plexuses is performed to diminish the formation of the fluid or if the spinal subarachnoid spaces are patent their continuous drainage into the peritoneal or retroperitoneal spaces or into a ureter after removal of a kidney may be attempted.

The surgical treatment of hydrocephalus, owing to the varying causative factors, has not been brilliantly successful except in those cases in which the removal of a bar, diaphragm or tumor could be accomplished. One is justified in undertaking surgical measures in all other conditions producing hydrocephalus to prevent further destruction of brain tissue and progressive increase of the intracranial pressure which would continue and lead to death.

INTRACTABLE PAIN*

Definition—Intractable pain is defined as that type of pain which does not yield to adequate and specific treatment of the underlying pathologic condition and which necessitates relief.

Etiology—The etiology of such pain is extremely varied and may range from disease of an unknown pathologic nature such as trigeminal neuralgia to lesions such as carcinoma of the bladder or malignant metastases to the spine. Among painful affections usually requiring relief of some sort may be listed migraine, trigeminal gloss-

* See the section on the Autonomic Nervous System.

sopharyngeal auricular occipital intercostal and anterior crural neuralgia, Raynaud's disease, angina pectoris, malignancies of all kinds both primary and metastatic tuberculosis of the larynx, tuberculosis of the genitourinary tract, gangrene or vascular insufficiency in the extremities of various etiologies, cruralgia, intractable peripheral neuritis such as chronic scurvy, herpes, injury, inflammation or inoperable neoplastic disease involving spinal nerve roots or the cauda equina, atypical facial pain of possible sympathetic origin, visceral pain of unknown origin and even dysmenorrhea. Rarely, cerebral disease, either cortical or thalamic, has been said to produce pain.

Treatment—The treatment of intractable pain depends on its origin its location the nature of the structures it involves the probable prognosis the life expectancy of the patient and his physical and psychological status. It should also always be understood that all possible underlying causes have been previously considered, investigated and specifically and sufficiently treated without avail by the most adequate methods including roentgen therapy, if indicated.

In general the subject of treatment may be classified under the headings of psychotherapy, medication specific and non specific, nerve injection and operation.

Psychotherapy—It is evident that pain is a subjective phenomenon may manifest itself in different degree in different persons. It is therefore necessary to evaluate patients and to form an opinion as to the actual presence of pain and as to its nature and intensity. There is no question but what the background of some pain is psychic and not organic, and it is also true that even tangible organic pain may be greatly exaggerated by some patients and minimized by others. Conditions which may affect these characteristics beside those inherent in the patient, are the type of pain the frequency of attacks the length of time pain has been present and additional factors such as drug addiction etc. Psychotherapy therefore enters in some measure into the alleviation of all painful afflictions perhaps most in facial and visceral pain of unknown origin and least in trigeminal neuralgia.

Medication—But few of the painful affections listed in this chapter are amenable

to specific medication. Chief among them are trigeminal neuralgia, angina pectoris and migraine. In about two thirds of all cases trigeminal neuralgia may be temporarily relieved by inhalation of trichlorethylene. This drug however loses its efficacy in a few months and over dosage with it is likely to produce undesirable effects such as nystagmus, tinnitus and vertigo. In the same way anginal paroxysms may be relieved for the moment by vasodilating compounds such as amyl nitrite. Migraine frequently responds to ergotamine tartrate.

Most pain however must be treated as far as drugs are concerned by narcotics. If there are contraindications to injection or operative therapy either because of inaccessibility or of the poor condition of the patient resort must be had to these substances. It is well however to give in small amounts as possible from the beginning since the demand usually becomes greater as time progresses, and the results of addiction are often as distressing as the original disease. Codeine is not habit forming and it is frequently feasible to give combinations of codeine, hypnotics and mild analgesics for some time before morphine or its derivatives become necessary.

Adjuncts to treatment by medication which are occasionally of value are the induction of local heat or cold and x-ray treatment.

Injection—The most direct method of dealing with intractable pain is to attack somewhere along its course the pathway by which it is conveyed from the painful region to the thalamus and sensory cortex of the postrolandic area of the cerebrum. The simplest and least permanently damaging device is the injection of various substances in or around the spinal or peripheral nerves.

Novocain is a useful drug for such purposes because it is a temporary but complete anesthetic. It is frequently therefore a good plan to precede further therapy by a diagnostic injection with novocain since this drug may serve to establish the presence of pain and to identify the particular nerves conveying it.

Saline solution is sometimes used by injection directly into a nerve trunk or around spinal nerves. The theory is that forcing large quantities of fluid into such areas has

a tendency to break up inflammatory adhesions which may be responsible for pain. The commonest sites for saline injection are the sciatic nerve into which it is injected for chronic sciatica and the epidural space at the lower end of the spinal canal into which it is injected for the relief of pain thought to arise in the filaments of the cauda equina as they leave the dura. It is felt by some that addition of various drugs such as novocain or quinine derivatives to the saline has a beneficial effect but most surgeons believe that any relief will be obtained as well by the use of saline alone.

Alcohol has long been used for nerve injection because its effect is to transect the nerve physiologically without destroying its continuity so that there is eventual regeneration. The usual strength used is 80 per cent in normal saline or in 1 per cent novocain-saline solution. Alcohol must be injected directly into the nerve itself in order to take effect since it does not infiltrate tissue as does novocain owing to its tendency to wall itself off by precipitating the tissue protein with which it comes in contact. It goes without saying that alcohol should not be injected into a mixed nerve the motor portion of which is essential to normal function.

Nerve injection with alcohol is a rather common procedure. The most frequent sites for its use are the various accessible divisions and branches of the trigeminal nerve the superior laryngeal nerves in tuberculosis of the larynx the intercostal nerves and painful amputation neuromas.

Injection of absolute alcohol into the dural sac has recently become a part of the therapeutic armamentarium for pain arising chiefly in the lower abdominal viscera and lower extremities. The patient is placed on his side and lumbar puncture is carefully performed at the first lumbar interspace. When the end of the needle is known to be in the subarachnoid space and not in contact with the conus medullaris and the upper part of the cauda equina which lie in that region 1 cc. of absolute alcohol is slowly injected. The side of the patient on which the pain is most severe is usually placed up-
permost since the alcohol will rise in the cerebrospinal fluid. The injection may be repeated once or twice at intervals of a week or ten days and a number of authors have

reported the obtaining of pronounced relief without the production of appreciable objective neurological signs. It should be borne in mind however that this procedure may eventually result in chronic inflammatory change in the central nervous system and it should therefore be limited in most cases to use in patients whose life expectancy or whose necessity for an intact spinal cord is not of long duration.

Operation—Operation on the central sympathetic or peripheral nervous system for the relief of intractable pain should be performed only when other means of alleviation are not indicated or have failed. It is a bad medical philosophy to interfere with a normal structure for the sake of a pathological one except out of necessity. Such operations however may become necessary and it is possible to classify them under the headings of neurolysis peripheral neurectomy posterior rhizotomy chordotomy and sympathectomy.

Neurolysis is the term used to describe the operative breaking up of perineural adhesions. It must occasionally be performed for pain arising in adhesions formed after injury particularly around the great nerves of the upper extremities. "Nerve stretching" of the sciatic nerve for chronic sciatica is also a form of neurolysis.

Peripheral neurectomy is performed in cases in which the pain seems to be limited entirely to the nerve in question as far as the conduction pathway is concerned. Nerves which may come into this classification are the supraorbital the glossopharyngeal the greater and lesser occipitals the cutaneous branches of the anterior crural etc. It should be remembered however that such nerves will regenerate if given an opportunity and that in the case of nerves which exit from foramina in the skull it is impossible to prevent regeneration. It is for this reason that neurectomies of the branches of the trigeminal nerve have given way entirely to alcohol injection when posterior rhizotomy is refused or inadvisable. The exception is the supraorbital nerve whose parent division cannot be injected because of its proximity to the third fourth and sixth nerves. In such cases neurectomy is better than peripheral injection because it is often possible to avulse several centimeters more

of nerve through the superior orbital foramen than could be reached by alcohol

The subject of peripheral neurectomy would not be complete without mention of the treatment of migraine by interrupting the dural sensory supply which follows the course of the meningeal vessels. This is accomplished by double ligation and division of the middle meningeal artery as it enters the skull through the *foramen spinosum*

Posterior rhizotomy is the section of a sensory cerebral or spinal nerve root central to its ganglion of origin. It has the advantage of producing a permanent sensory loss because of the absence of regeneration owing to the lack of neurilemma sheath and of causing no interference with motor function. Except in the case of trigeminal neuralgia however this operation has lost favor in recent years except in cases in which pain arises from isolated spinal nerves such as that seen in persistent intercostal neuralgia or in intractable lumbic root pain. The reason for this is the tremendous overlap in the areas supplied by spinal nerves which necessitates the sectioning of many more roots than is practical in order to produce the desired anesthesia

Chordotomy is the operation which has largely supplanted posterior rhizotomy. It consists in sectioning that portion of the spinal cord which contains the lateral spinothalamic tract and conveys the sensations of pain and temperature. The accompanying diagram shows this area (Fig. 193). A small part of the anterior gray column has also been included since some observers believe that visceral sensation is herein carried cephalad by short chain pathways

The section illustrated will produce analgesia up to a point within a segment or two below the level of the operative lesion on the side of the body opposite to that on which the lesion is made. Bilateral chordotomy will of course produce bilateral analgesia and it can be done at any level up to the midcervical region in which the phrenic nuclei are situated. Unilateral chordotomy in the middle or upper cervical cord is sufficient but a bilateral operation here particularly as a one step procedure is fraught with danger of respirators paralysis

This operation is at present the best known and the one most frequently used for

the relief of intractable pain. A properly performed unilateral lesion is entirely benign. Bilateral lesions however produce a loss of ejaculatory reflex although they do not otherwise render patients sexually incapacitated and they also frequently cause temporary though not often permanent loss of sphincter control

A recently proposed variant of chordotomy which should be mentioned is the production of an artificial syringomyelia by division of the median commissures of the spinal cord. This results in a localized bilateral loss of pain and temperature sensation its extent being dependent on the length of cord involved in the operation. It may prove a useful substitute for the dangerous high cervical bilateral section of the anterior lateral tract

Fig. 193—Diagram showing portion of spinal cord sectioned in the operation of chordotomy for the relief of intractable pain

Sympathectomy is in some respects the most recent addition to the list of procedures for the relief of pain. Periarterial sympathectomy is a fairly old operation but in recent years operations on the main sympathetic pathways have come more into favor. Section of the hypogastric plexus is performed for pain arising in the bladder or internal genitalia. In the lumbar sympathetic chain for painful vascular disease in the lower extremities and of the thoracic and cervical sympathetic system for angina pectoris, Raynaud's disease and emphysema

Most of these procedures afford relief in some cases. However it is but fair to say that many have not stood the test of time. Nevertheless they are always to be seriously considered because of the possibility that they may be successful in otherwise desper

ate and intolerable situations, and they have the additional advantage of not interfering appreciably with essential bodily functions and even of being therapeutically helpful with respect to the underlying pathological condition, as in the case of Raynaud's disease

XIV. ORTHOPEDIC SURGERY

TUBERCULOSIS OF THE BONES AND JOINTS

History—Since the earliest days of medical history the pathologic condition now known as tuberculosis has been recognized. Its clinical character separates it from the more acute infectious processes. Long before Koch (1881) discovered *B. tuberculis* this disease was known as white swellings, scrofula and surgical tuberculosis. For signs of acute inflammation were absent and the gross pathologic picture was that of multiple tubercle formation. Koch's momentous discovery with the classic application of the postulates established the infectious nature of this disease.

Etiology and Pathology—The infecting organism in tuberculosis may be of the human, bovine and rarely avian type as identified by cultural and morphologic characteristics. In the infectious processes of the bones and joints of man the human and bovine types of organism predominate. Infection is by direct or indirect contact with an open case or by ingestion of contaminated food. It follows contact with an open case of pulmonary tuberculosis cases with draining sinuses or the ingestion of contaminated milk. Bone and glandular infections have a high incidence where the supervision and inspection of dairies is inefficient. Hereditary or prenatal infection is improbable. The natural resistance to *B. tuberculis* is high when the quantitative infection is small as evidenced in the survival of the human race. The majority of persons having tuberculosis in an arrested form.

The susceptibility of different races to this infection differs. The Negro, Mexican and Indian are only slightly resistant. The yellow race is slightly more so while the white race has the greatest resistance. Sex seems to have no influence on the incidence of this infection. Infections of the bones and joints predominate in early life. A large majority occurring between the ages of one and six years.

The joint or bone lesion is always secondary to pulmonary, gastrointestinal or glandular foci. The occurrence of a lesion in bone indicates that the resistance of the soft tissue is high. The route of infection is un-

doubtedly hematogenous; minute emboli of organisms lodging in the small capillaries adjacent to the epiphyseal cartilage.

The implantation of emboli is due to the peculiar anatomical arrangement of the smaller blood vessels prior to epiphyseal closure. Small infarcts form. Typical tubercles develop and grow circumferentially, destroying bone without stimulating reparative reaction and forming local abscesses. Extension to the joint results from destruction of the epiphysis and articular cartilages or by extension along the epiphyseal line to the capsule and synovium. Osseous or synovial pathologic conditions result. The involvement of the synovium is accompanied by signs of irritation; the amount of synovial fluid is increased and movement is restricted. Bone atrophy is common. The articular cartilage is detached by subchondral extension of granulation tissue. A tuberculous process differs from an acute pyogenic condition in that there is no redness or local heat. The swelling remains as the 'tumor albus' or 'cold abscess'.

Diagnosis—Clinical diagnosis is made late in the course of the infection for the course is insidious and the signs are indefinite. Three clinical types of pathology are found: (1) *cries sicca* in which the onset is insidious, the progress slow and no abscess is formed; (2) *acute* when signs are fulminating as in pyogenic joints; and (3) *subacute* when the symptoms are moderate but progressive. In a small percentage of cases bone or joint lesions may be multiple.

Symptoms—The symptoms of tuberculosis of a joint reflect the disruption of the normal physiology of the various joint structures. Swelling is most constant and is recognized by inspection, palpation and measurement of the joint. The normal joint markings are lost by the boggy thickening of the synovial structures. Muscle spasm which restricts joint movement so as to prevent greater irritation is always present. The tuberculous joint is usually monoarticular thereby permitting comparison with the nor-

mal range of function of the uninvolved articulation

Atrophy of the adjacent soft structures though not diagnostic suggests the involved extremity. Pain is variable and not specifically diagnostic. Loss of length results from deformity, destruction of bone and disturbance of the normal epiphyseal growth. Characteristic deformities result from positions assumed for comfort from muscle contractions and also from bone destruction. The general symptoms such as loss of weight, secondary anemia and low grade temperature are frequently absent.

The clinical picture is never diagnostic for it may be simulated by many other types of infection. Positive diagnosis is made by the identification of B tuberculosis in tissue obtained at biopsy or aspiration by the typical histopathologic tubercle formation or by recovery of B tuberculosis by injection of infected material into the guinea pig. Dermal tests with tuberculin are useful in distinguishing the non tuberculous from the tuberculous patient, the reaction being positive only in the presence of tuberculosis.

Atrophy and destruction of bone alterations of the joint space and the formation of an abscess revealed by the roentgenogram although not specific have diagnostic value. An early accurate diagnosis is necessary to prevent overtreatment of non tuberculous and undertreatment of tuberculous lesions.

Treatment—Up to the present no specific treatment for tuberculosis has been generally recognized. Preventive measures have made great strides and a lowered incidence results. Isolation of open cases and strict supervision of the milk supply have effectively reduced the number of tuberculous cases.

Treatment is along general as well as local lines. Wholesome hygienic living conditions, fresh air and a generous well balanced diet high in calcium and phosphorus salts are essential as is rest. General and local Heliotherapy as popularized by Rollier is important and is indicated as an adjunct to local measures but exposure should be graduated and not overdone. During winter months the quartz mercury and carbon arc lights in moderate dosage are useful.

Local treatment consists of promoting functional rest in the involved joint by the

use of traction braces and splints and by surgical ankylosis. Abscesses are aspirated and treated without drainage unless secondarily infected. Deformity is corrected by traction manipulation or operation.

TUBERCULOSIS OF THE SPINE

Pathology—Tuberculosis of the spine (Pott's disease) is first in incidence among osseous tuberculous lesions. It is more frequent in children but may occur at any age.

Fig 900—Pott's disease involving the lower lumbar area showing destruction of the vertebral bodies and its relation to the terminal roots of the spinal cord.

The sites of tuberculous lesions in order of frequency are the lower dorsal, upper dorsal, upper lumbar, lower lumbar and cervical vertebrae. The intervertebral process is located along the cartilage plate of the vertebral body, resulting in early absorption of the intervertebral disks and destruction of the adjacent areas of the vertebral bodies. Bone destruction is followed by collapse of the vertebral bodies and posterior angulation (*kyphosis*). Multiple areas of involvement are not un-

common. Abscesses form early. In the cervical region the abscess extends anteriorly, compressing the soft structures of the neck and at times extending extrapleurally into the upper portion of the thorax. In the dorsal area the abscess remains localized and is globular, giving evidence of posterior mediastinal pressure. Abscesses arising from the lower dorsal and lumbar portions of the spine extend along one or both psoas sheaths to the pelvis (*psoas abscesses*), at times pointing in the femoral area after passing beneath Poupart's ligament. Less frequently lumbar involvement gives rise to abscesses pointing posteriorly in the lumbar area.

Symptomatology.—The symptoms of tuberculosis of the spine are irritation, compression of adjacent structures or interference with the function of the spinal cord and spinal nerve roots.

All movement of the spinal column is restricted by muscle spasm, motion and attitudes are protective. With cervical involve-

squatting position. Irritation of the spinal cord and nerve roots results in the reference of symptoms to areas remote from the area of the disease. Tension arising from abscess formation within the psoas sheath may suggest disease of the hip joint.

Fig. 201.—Tuberculosis of the upper lumbar spine with deformity.

ment, rotation of the neck is restricted or absent, and the patient supports the chin with his hands. In cases of dorsal involvement, interference with motion is somewhat less marked but is evident on flexion. Instead of flexing the spine in picking up objects from the floor, the patient assumes a

Fig. 202.—Roentgenogram showing tuberculosis of the spine at dorsolumbar juncture. Bilateral psoas abscess with marked calcification.

Deformity is a late manifestation of vertebral disease. Angulation is posterior and is in the sagittal plane except in rare instances. Multiple areas of disease may give rise to long, rounded kyphoses rather than the usual sharp angulation.

Involvement of the spinal cord is seen in the development of signs of transverse myelitis, in the more advanced stages, in complete paraplegia.

Diagnosis.—The diagnosis of vertebral tuberculosis is confirmed by changes in the roentgenograms. The intervertebral space is thin, deformity is evident, bone destruction is present and aspiration of abscesses may yield B. tuberculosis.

Treatment of vertebral tuberculosis consists of all measures employed in a general type of the disease combined with immobilization of the spine, accomplished by rest in bed, support on a firm frame, plaster shell or

brace until healing by bony consolidation of the diseased area is complete. Prolonged recumbency is necessary. Internal splinting may be accomplished by a spinal fusion op-

the marginal epiphysis of the acetabulum or the synovial structures of the joint. Bone destruction may be limited to the upper end of the femur or to the acetabulum. Hip

Fig 203—Tuberculosis of the spine Showing the use of a hyperextended Bradford frame.

eration or by means of a bone graft in order to solidify the pathologic area. Abscesses are aspirated through firm tissue and drained if secondary infection is present.

disease usually occurs in children under ten years of age, and trauma undoubtedly plays an important rôle in the localization of the disease by lowering the local resistance.

Symptomatology.—In the early stages of infection of the hip joint the symptoms are

Fig 204—Tuberculosis of the right hip. Fixation in plaster splint after operative fusion.

TUBERCULOSIS OF THE HIP

Pathology.—The incidence of tuberculosis of the hip joint is second to that of vertebral tuberculosis. The initial lesion is located in the epiphysis of the upper end of the femur,

Fig 205—Tuberculosis of the spine. Support obtained with a spinal brace.

transient and evidenced by a slight limp. Signs of irritation gradually become more marked, and muscle spasm in all directions increases. The thigh is flexed and adducted causing the leg to appear short. In the early stages, pain is referred to the medial aspect

of the knee joint along branches of the obturator nerve. Atrophy of the buttock and thigh is recognized by inspection, palpation and measurement. Abscess formation often is extensive.

Diagnosis.—Roentgenologic examination reveals capsular swelling, bone atrophy and destruction of the femoral head or acetabulum, or both. Subluxation may be present

TUBERCULOSIS OF THE KNEE

Etiology and Pathology.—Tuberculous infection of the knee joint is always secondary to a primary lesion involving the lungs or the gastrointestinal tract. Transmission to the knee joint is through hematogenous channels. In children the bacterial emboli lodge in the epiphyseal cartilage forming a localized tubercle. This focus increases by

Fig. 206.—a, Tuberculosis of the right hip of five years' duration. b, roentgenogram made two years after a fusion operation.

A positive diagnosis is established by aspiration and in some cases by biopsy of the diseased area.

Treatment.—Local treatment consists of immobilization of the joint in a position favorable for function after ankylosis of the joint. Traction, casts and splints are used extensively. Fixation of the joint by operation is the procedure of choice of many surgeons, as the ankylosis of the joint is more rapid and prolonged recumbency is avoided

progressive destruction of bone and enters the knee joint by extension along the capsular structures or directly through the articular tissues. Within the joint the synovial response is that of irritation. A synovitis is present as is indicated by the increase of synovial fluid, normal landmarks of the joint are lost and the synovia becomes thickened and studded with tubercles. Pannus formation covering the articular surfaces is common.

Symptomatology.—The joint disability parallels the destruction of the various joint structures. The muscles of the thigh are in spasm and soon show signs of atrophy. Active and passive motion of the joint is painful. Roentgenograms reveal the location of the destructive process along the epiphyseal line with occasional sequestrations (Fig 209, *a*). Atrophy of the bone adjacent to the joint is present. As the disease progresses, destruction of the epiphysis becomes more marked, and abscesses form and

joint conditions. A positive reaction to tuberculin, although not positive proof as to the infectious agent, facilitates diagnosis. In order to prevent overtreatment of a non-tuberculous joint and undertreatment of a tuberculous joint, an accurate diagnosis is essential. This is obtained only by recovery of *B. tuberculosis* on aspiration or biopsy.

Fig 207—Heavy grafts (A and B) of cancellous bone are reflected from the anterolateral and posterolateral aspects of the greater trochanter. The periosteal and muscular attachments of these grafts are not disturbed. A massive graft including the greater trochanter, lateral surface of the neck and a portion of the cortex of the shaft is removed by converging cuts.*

extend along fascial planes. The popliteal lymph glands increase in size and may break down, forming sinuses.

Diagnosis.—The early clinical picture of such a condition in the joint cannot be accurately differentiated from other types of infection without specific data. In a child below the age of six years, the reaction to tuberculin is significant. A negative von Pirquet or, better, a negative intradermal tuberculin test (Mantoux) is useful in ruling out tuberculosis in otherwise questionable

Fig 208—The trochanter graft is turned end for end and shaped for maximum contact. The cortical portion is then driven firmly into the recess on the lateral surface of the ilium. The thigh is abducted to establish firm contact with the graft. The osteoperiosteal grafts are firmly sutured over the free end of the massive trochanteric graft, and the wound is closed without drainage.*

aided by guinea-pig inoculation, or by the identification of the tubercle in the involved tissue. In adults the clinical picture is of a low grade synovitis of a progressive nature. The onset is insidious, the swelling is marked but redness and pain except on motion are noticeably absent. Roentgenograms show bone atrophy with or without destruction of bone.

Fig 209—*a* Tuberculosis of the knee with destruction of the articular surfaces *b* after an operative removal of the knee joint

Local rest of the joint is important and may be accomplished by the use of splints, casts and braces. With this regime arrest of the disease process is favorable but extremely slow. With the most satisfactory progress, healing of the lesion with the preservation of useful motion is the exception rather than the rule, as verified in the treatment of joint disease in adults.

Operations to rid the process of ankylosis in adults are well accepted and widely employed, but in children the operative course has been less favorably received, most surgeons preferring the prolonged fixation in

at the upper end of the tibia is removed and the semilunar cartilages are excised. The denuded surfaces of the femur and tibia are altered to correct any deformity. A mortise is then cut in the femur and tibia to receive the patella which is used as a graft. After the articular cartilages have been removed the patella is placed in the recesses of the femur and tibia and locked into place by extension of the joint.

The crucial and collateral ligaments are not disturbed and no attempt is made to remove patellofemoral synovitis. The incision is closed without drainage and a splint cast applied at 20 degrees of flexion being desirable in adults. In children full extension of the knee is desired because of possible yield through the epiphysis. Early weight bearing is permitted. Bony union occurs in a high percentage of cases in six or eight months.

Fig. 211—A Tubercles of the carpus. B One year after excision of the carpal lesions (film reversed)

plaster splint or brace during the period of growth.

Surgical treatment is directed toward the establishment of a bony ankylosis of the knee joint. Of many different procedures suggested and used only the knee fusion of Hibbs will be described here.

A tourniquet is used for hemostasis. A curved incision is made across the anterior aspect of the knee joint extending from the lateral surface of the medial femoral condyle across the center of the patellar tendon and through to the lateral aspect of the lateral femoral condyle. The skin flap is turned up from the anterior surface of the patella. The incision is then carried through the aponeurosis, capsule and patellar tendon to permit the complete upward rotation of the patella. The joint is flexed. The articular cartilage of the femur

TUBERCULOSIS OF THE ANKLE

Tuberculosis of the ankle and tarsus is less frequent than tuberculosis of the spine, hip and knee but more frequent than involvement of the joints of the upper extremities. Synovial thickening is marked, abscess formation with subsequent sinuses frequently occurs. Roentgenograms show destructive lesions of the bone with loss of joint space. The diagnosis is verified by means of culture and guinea pig inoculation of aspirated material. Treatment consists of prolonged immobilization in a plaster cast or brace and operative ankylosis. In rare cases amputation is indicated. Ankylosis with the foot in good position is the most desirable result.

TUBERCULOSIS OF THE SHOULDER

Tuberculosis of the shoulder may be the dry (eries sicca) or the moist type. The disability is great because of the usual adducted position of the humerus. Diagnosis is established by means of clinical examination, the characteristic changes revealed by roentgenogram and aspiration or biopsy. Treatment consists of promoting ankylosis with the humerus in a position of 60 degree abduction.

TUBERCULOSIS OF THE ELBOW

A tuberculous elbow bears the best prognosis of any joint for healing with some useful degree of motion. Fixation at right angles with plaster or a splint is indicated. Operative fixation should be carried out in resistant cases.

TUBERCULOSIS OF THE WRIST

Tuberculosis of the wrist may be primary in the wrist joint or secondary to disease of the carpus or metacarpals. The disease spreads rapidly to the carpal joints and adjacent soft structures, and the disability is great. Prolonged fixation with the hand in 30 degree extension is indicated. Fusion of the carpal bones gives favorable results.

STATIC DEFORMITIES OF THE SPINE

As in other parts of the skeleton there is a group of deformities of the spine generally known as static deformities, i. e. developing under the influence of weight bearing. To these belong a large part of the anteroposterior deviations or kypholordoses and of the lateral curvatures of the spine or scolioses. All one can say to justify the term 'static' is that gravitational stresses play a major part; it cannot be the sole nor the ultimate cause of the defect, since gravitational stresses are universal while the response of the spine to these stresses by assuming a deformity is exceptional and hence pathologic.

The mechanical function of the spine is that of (1) a sustaining rod maintaining the upright position and carrying its weight, (2) a point of anchorage for the powerful muscles of the shoulder and pelvic girdle as well as of the trunk, (3) a buffer spring receiving and distributing in rapid and endless sequence innumerable jars and jolts associated with the dynamic function of the body, (4) a casing of safety for the delicate nervous structure within the spinal canal and for the peripheral nerves issuing therefrom, and (5) an organ of great flexibility subservient to the motor functions of the whole body.

In any of these mechanical functions or in any combination of them the spine may fail because of some underlying local or general causes. Failing as a sustaining rod from weakness or insufficiency of the musculature which supports it and which controls its position, it will assume an anteroposterior or lateral curve. Failing as a buffer spring in its function of weight distribution, it will cause secondary changes in the bodies and disks which often result in the total loss of the elasticity and of much of the flexibility of the spine. Failing as a safe casing for the nervous structures, it will cause irritation or suppression of motor and sensory impulses and finally failing in its flexibility, it must necessarily detract from the motor function of the entire body.

What causes these various functions to fail singly or in combination? It is most important for the management of the patient to establish the underlying condition leading to the functional failure of the spine. There are of course definitely localized pathologic lesions which lead to spinal deformities, tuberculosis of the vertebrae, osteomyelitis, trauma and malignant growths. But the group under consideration in this chapter is the one in which the spinal deformities are assumed to be due to a general cause. Here, therefore, it was necessary to be satisfied with such meaningless terms as "habitual insufficiency," but with a better understanding the underlying causes become more tangible and there are being recognized such conditions as constitutional hypoplasia, early or late rickets, developmental growth disturbances, regressive and degenerative changes of the vertebra and disks, myasthenia and paralytic factors, etc., as underlying reasons.

for the mechanical failure and the subsequent deformities of the spine

THE ANTERIOPOSTERIOR SPINAL DEFORMITIES KYPHOSIS (HUMP BACK) LORDOSIS (SWAY BACK) AND THEIR COMBINATIONS

The So Called Static Malposture—*Definition*—When is posture abnormal? Posture must be defined in terms of the relationship of the line of gravity to the landmarks of the human body and not as is commonly done by the relationship of the body parts among themselves. In a normal upright stance the line of gravity rising up

diaphragm being most favorably balanced for respiratory function the narrow back or carnivorous type (the slender anatomical type of Willis) with a long narrow chest a small costal angle and a tall slender long body often with high palate and hypertrophied tonsillar and adenoid tissue and the broad back or herbivorous type (heavy anatomical type of Willis) with a large heavy skeleton a wide costal angle a high diaphragm heavy flat and broad vertebrae a short lumbar region a broad and deep abdominal cavity in contrast to the former group the fifth lumbar vertebra is situated low between the ilia the sacrum is more per

Fig 210—Anatomical types of back. *a* Normal type with moderately rounded thorax. *b* slender type of Willis. *c* heavy type of Willis. *d* round hollow back from normal type. *e* flat back. *f* round hollow back, heavy anatomical type.

in front of the ankle joint and close to the knee joint axis intersects with the spine at the lumbodorsal and cervicodorsal levels to reach the mastoid process. In abnormal posture or malposture this relationship is changed and the line of gravity is deflected usually behind sometimes in front of the normal points of intersection; there is a radical change of the gravitational stresses throughout the body and hence also a complete rearrangement of muscular and ligamentous resistance against gravity.

Classification—Goldthwaite distinguishes three anatomical types: the normal type with moderately rounded thorax and high

pendicular and the mobility of the lumbar spine is rather restricted (Fig 212 *a b c*).

Types of Malposture—*a* From the normal type develops the round upper and the round hollow back. The former represents a relaxed position the shoulders dragging downward and forward and the pelvis becoming more horizontal; *e* the angle of inclination is lessened. The line of gravity is shifted backward. In the round hollow back the kyphosis of the upper trunk is recovered by a compensatory lordosis so that the line of gravity is little deflected. This type therefore approaches physiologic limits (Fig 212 *d*).

b The slender anatomical type produces the flat back, the body is carried backward by hyperextension in the lumbar region making a sharp curve at the lumbosacral level. The line of gravity is deflected strongly backward, in the round back of this type there is a total posterior curve with the cervical spine in strong hyperextension to bring the head into the line of vision. The pelvis is horizontal the hips are hyperextended and the line of gravity shows less backward deflection (Fig 212 c)

c In the heavy anatomical type there also develops a round hollow back as in the normal type with increased dorsal kyphosis and lumbar lordosis but the pelvis retains its normal position (Fig 212 f)

Malposture and Visceroptosis—Here one deals primarily with a disturbance of the thoracic and abdominal balance due to the weakness and relaxation of the muscles of the abdominal wall and of the pelvic floor. In necessary sequence a malposture develops in which the upper portion of the trunk is thrown backward. *Licet versa* postural anomalies acquired in youth are very apt to predispose to visceroptosis. Statistics show that in children the incidence of visceroptosis with malposture is great.

Rachitic Kyphosis—This condition is the remainder of the physiologic anteroposterior curve of the newborn but because of the weakness and relaxation of the muscles of the back and the softness of the bones the erection of the spine is not accomplished. When a child stands up an attempt is made to compensate the low dorsal rachitic curve by low lumbar lordosis so that the typical malposture is that of a round back or round hollow back.

The nature of the deformity is revealed by rachitic stigmas. The thorax is compressed from side to side so that the anteroposterior diameter of the chest exceeds the lateral one (Freiberg). Owing to the long continued forward flexion at an early age there are marked secondary rachitic changes of the thorax most frequently pectus excavatum or funnel chest, then the sternum is depressed the lower ribs flare out and in the lower thoracic region the lateral diameter exceeds the anteroposterior (Fig 213 a)

Malposture in Osteochondritis Deformans Vertebrae—It was believed that this

condition is due to a definite disturbance in the ossification process of the vertebral epiphyses or vertebral epiphysitis (Dela Haye Schuermann), which becomes apparent about the twelfth year of life. Schmorl's investigations and those of his pupils and followers however indicate that the disturbance in the growth and form of the vertebral body is due rather to changed relations between the body and the intervertebral disk the nucleus pulposus often herniating in small nodules into the softened vertebral spongy substance (Schmorl's

Fig 213.—a Rachitic kyphosis. b malposture in osteochondritis deformans

nodules). The result is an anteroposterior kyphosis as an expression of an exaggerated physiologic curve and the vertebrae become more or less wedge shaped (Fig 213 b)

Calve described a localized affection of disturbed enchondral ossification of the body and the latter appears fragmented and its outlines blurred. It is followed by a process of reparation and ends up in a wedge shaped deformation of one or two vertebrae. This condition is observed at a much earlier age.

The clinical symptoms of osteochondritis vertebrae are fatigue, backache, pain in the limbs and tenderness of the spinous processes over the involved vertebrae. In the earlier form there are sometimes night cries and muscle spasms.

Treatment of Anteroposterior Deformities—General—The primary objective of general treatment is to improve the underlying constitutional condition. This is car-

Fig. 214—After operative treatment

ried out by such local measures as removal of the tonsils and adenoids so as to develop free upper air passages and an efficient respiratory function and by a general hygienic regime including recommendations for an

shoulder girdle by appropriate exercises (Lovett). They are taken both in a standing position and lying down.

In the correction of deformity exercises play an important role in developing and maintaining the muscular tone which is a safeguard against progression especially when a noticeable degree of visceroptosis accompanies malposture. Such special thoracic and abdominal exercises are of greatest value. The beneficial effect of this type of gymnastics is likewise very evident in patients with rachitic malposture and is less so in those with a paralytic or arthritic background.

Correction—For the actual correction of the already developed deformity exercises and massages important as they are are usually not sufficient. In more severe cases the question of more forcible correction by corrective casts must be considered. To what extent is this possible? This is a question which must be answered with due regard for the type of the deformity, the rigidity of the curve, its duration and the age of the patient. The single curve in the flat and round back is more amenable to gradual correction by means of a cast than the double curves of the round hollow back where improvement is more apparent and usually due to the development of counter curves. Telsons

Fig. 215—Spring back body braces

open air life, tones and an adequate diet in order to raise the constitutional resistance.

Prophylaxis—The prophylaxis of the deformity is based principally on muscle development especially of the back and

technic follows this point by first abolishing the lumbar lordosis in a cast put on in strong forward flexion; then the dorsal kyphosis is corrected by bending the trunk backward over the upper edge of the cast. Naturally

children under six or eight years of age with a more flexible curve usually rachitic are better subjects. In the prepubertal age especially in the osteochondritic type of mal posture, it must be remembered that because of its anatomical change the deformity "sets" rather early, and by the time the age of fourteen or sixteen years is reached real anatomical correction is very difficult (Fig 214)

Symptomatic.—Supports must be worn such as reinforced corsets with shoulder straps in milder cases or steel braces in more severe cases during the period of muscle development and after corrective cast treatment until the period of convalescence. The reasons for this treatment are twofold. First the subjective symptoms of fatigue and back pain demand special support, second the development of muscle tone so important in the treatment must not be jeopardized by leaving the trunk muscles without safeguard during the critical period (Fig 215)

THE LATERAL DEFORMITIES OF THE SPINE SCOLIOSIS

When under certain conditions the normal equilibrium of the spine becomes lost so that it is no longer under active muscle control and has lost its ability to revert to symmetry promptly from any asymmetrical position, the spinal condition must be considered as being pathologic and as undergoing deformation. The deforming process is beyond voluntary control and is progressive being halted only from time to time by the resistance of the tissues—bones ligaments and muscles. In the lateral deformities of the spine the same as in the anteroposterior a number of different underlying causes may be at work which are responsible for the normal loss of muscular control of spinal symmetry and which lead to permanent lateral deviation or scoliosis.

Types.—A number of these causes are due to congenital defects in the architecture of the spine, in others muscle control is lost by paralysis of the spinal muscles in a third group general metabolic changes which involve muscles and bones are at fault (rachitic scoliosis), and finally as in the anteroposterior deformity, there is also the group of constitutional causes the so called habitual

scoliosis to which no definite tangible factor has so far been assigned. This forms a large group simply because in so many cases one is not able to recognize the etiological factor beyond the vague assumption of a constitutional deficiency.

Congenital Scoliosis.—The morphological anomalies are principally the wedge formation the rudimentary development of single vertebrae the clefts of the arches (the so called spina bifida occulta or manifesta) or other architectural displacements of the spine. Although the morphological anomalies are scattered over the whole length of the spine the fifth lumbar vertebra is a favorite point and a most effective one in the production of congenital scoliosis since it joins the free spine to the rigid pelvic girdle. Similarly anomalies of the cervical and upper dorsal spine produce scoliosis which often cause asymmetry in the shoulder girdle for instance elevation of the scapula (Fig 216 a)

Rachitic Scoliosis.—One may distinguish three types (1) a lumbodorsal or lumbokyphoscoliotic form the direct sequence of the usual low dorsal or lumbodorsal anteroposterior rachitic curve (2) a combined type localized in the (more often right) lumbar region and associated with an opposite high dorsal curve and (3) the high cervicodorsal type. The last one is the most characteristic though not the most frequent of all rachitic curves (Fig 216 b)

Paralytic scoliosis is a sequela of infantile paralysis and should be anticipated wherever there is extensive paralysis of either the upper or the lower extremities. It follows no particular type since it depends entirely on the distribution of paralysis.

Bilateral symmetrical paralysis of the musculature of the back usually leads to simple lordosis while symmetrical paralysis of the abdominal muscles usually causes the round hollow or round back type of anteroposterior deformity.

In unilateral symmetrical paralysis of the muscles of the back a lumbodorsal or dorsal curve develops in the spine the convexity as a rule pointing to the sound side.

In paralysis of the upper extremity and shoulder girdle a scoliosis develops in the high dorsal region after an interval of latency. If the deltoid and biceps muscles

are paralyzed the effort of the patient to abduct the arm by side bending will facilitate the development of a scoliosis with convexity to the affected side especially if there is also paralysis of the anterior serratus so that the shoulder blade is pulled up by the unopposed action of the trapezius muscle (Fig 217 a)

So Called Habitual Scoliosis or Idiopathic Scoliosis—This term merely indicates the absence of a definite underlying cause. It implies a general or constitutional predisposition such as anatomical build and general habitus or inherited or acquired weak-

Unusual Forms of Scoliosis—1 The hysterical type is a true contracture a pure inclination deformity and not a true scoliosis characterized by a total curve with the apex at the lumbodorsal junction

2 The so called sciatic scoliosis due to involvement of the sciatic nerve is likewise not a true scoliosis but an involuntary postural inclination due to muscular contracture following back injuries with sciatic radiation

In neither of these types is there a rotational element hence they cannot be classified as true structural scolioses

Fig 216—*a* Congenital scoliosis *b* rachitic scoliosis

ness or relaxation of the spine and its musculature. Insufficiency of the spine is another term which is frequently used but it has no meaning and no concrete tangible pathologic factor has as yet been assigned definitely as the cause of this type of scoliosis. Recent investigations as to the role of the intervertebral disk are likely to throw some light on the pathogenesis of this condition. There are usually two types: the right dorsal with a secondary lumbar curve and the left total type of scoliosis. The majority of cases occur in females (Fig 217 b)

3 The so called static scoliosis is the result of inequality of the legs. It is likewise merely an inclination deformity of the lumbar spine. The mobility of the spine is retained and there is no rotation for a long time yet a true structural scoliosis may ultimately develop from it

4 Scolioses are observed occasionally in spastic paralysis and in tumors of the spinal cord. These are also contractural forms and there is lack of rotation

5 The scoliosis in tabetic arthropathy of the spine is a true collapse deformity. So

also that seen in the osteoporosis of the spine or in severe osteoarthritis in persons of advanced age

6 In empyema again a lateral curvature of the spine is often observed which is a simple contracture caused passively by the pull of the empyematic scar accordingly it shows no rotation

7 *So Called Traumatic Scoliosis*—Of greater interest is scoliosis following trauma In the majority of these cases there have been crushes or fractures of smaller portions of the vertebral bodies and their processes In the dorsal region it often follows a compression fracture of the sixth to the ninth vertebrae In the lumbar region most cases of traumatic scoliosis are due to fractures of the fifth lumbar vertebra Post-traumatic effects on the disk are often expressed by degeneration and shrinkage and these may lead to the habitual assuming of an asymmetrical position and to habitual deformity

Pathology—Scoliosis is a combination of lateral deformity and longitudinal rotation Both factors are inherent and indispensable parts of the deformity The lateral deviation is brought about primarily either by an inclination of the vertebrae against each other, as in the paralytic type of scoliosis or by a side shifting of the bodies against each other as in rachitic and senescent scoliosis The first mechanism is called the *inclinationary* and the second the *collapse type* The first is characterized by a wedge deformation of the vertebral body with the basis toward the convexity, the second by an oblong trapezoidal deformation the so called *lique vertebra* Later both types become so closely interrelated as to present one vertebral deformity

The rotatory element of deformity is always present taking place both in the intervertebral articulation *i e* from vertebra to vertebra and within the structure of the vertebra itself This structural rotation is often called *torsion* Both rotation proper and torsion constitute the rotatory deformity

It is not only the vertebral bodies but also the neural arch with the transverse articular and spinous process which take part in the rotation deformity, they are kinked against the vertebral bodies the angle open-

ing on the concave side of the curve, the intervertebral foramen becomes egg shaped with the small pole also to the concave side the pedicle and arch are thinned out toward the convex surface and shortened and thickened toward the concave surface

The most striking rotation effect is seen in the thorax As a result of the backward rotation of the body and transverse process on the convex side the rib on that side is curled against the body and process and becomes sharply bent while on the concave side it appears to be stretched away from

Fig 217—*a* Paralytic scoliosis *b* lateral scoliosis

the vertebrae and flattened out This produces in the back the characteristic costal projection or hump on the convex side and the hollow and flattiness on the concave side In front conversely, the flat concave side ribs project sharply lateral to the sternum while the buckled convex side ribs appear flat so that the projections in front are reversed In the deformation of the thorax the spinal column leads and the ribs follow however the ribs are not being deformed by the twist of the spine alone but also by other mechanical factors the most important of which is the side pressure of the

muscles of the thoracic cage and of the abdominal walls

Prophylaxis—When the scoliotic deformity is developed with the marks of lateral and rotation deformity and of permanent loss of symmetry of the spine it is with very few exceptions too late to expect complete anatomical restoration. Hence the most important aspect of the management of the condition is prophylaxis.

How is scoliosis to be anticipated and prevented? In the congenital type one cannot properly speak of a prescoliotic stage yet there is a long period of latency during which the spine is able to maintain its equilibrium in spite of congenital architectural defects. The deficiency is first indicated by occasional postural anomalies and asymmetries and it can at this stage be recognized and held in check at least for a time by systematic muscle training.

In the rachitic type prophylaxis is important. The prescoliotic stage also appears in the form of attitudinal anomalies which however are rather characteristic anteroposterior curves and signify not so much muscular insufficiency as relaxation of the costovertebral junctions and of the intervertebral articulations.

So called habitual or idiopathic scoliosis has always received considerable attention from the viewpoint of prophylaxis. It has been called school scoliosis because it is believed to develop during the school age; some investigators have found as high as 20 or 30 per cent of all school children afflicted with this functional scoliosis as a result of faulty posture. However the usual prophylactic measures are as a rule belated. The critical age is between the third and fifth years and it is at this time that prophylaxis should be practiced.

In paralytic cases it is difficult to speak of prophylaxis. A long silent interval usually exists between the onset of paralysis and the first appearance of scoliosis. One should be prepared for it however in all cases of severe involvement of the extremities. It is very difficult to recognize differences in the muscle strength of both sides of the back. Because of the rapid progression of this type of scoliosis even the slightest suspicion of asymmetry calls for energetic preventive measures.

Treatment—Treatment should consist in (1) the correction or improvement of the deformity either by flattening the existing curve itself both in the lateral and rotatory sense or by developing contralateral counter curves above and below the original one which offset the lateral and rotatory deflections of the body (compensation) and (2) the maintaining of any correction or improvement either by a systematic development of the back muscles or by abolishing motion in the intervertebral junctions and by stiffening of the spine.

It is obvious that different patients will respond differently to one or the other of the alternatives by which these two objectives may be advanced. Yet before discussing the methods the following facts should be considered.

a. In the great majority of cases the original curve is so resistant that attempts at correction either by manipulation casts or redressment so called will result in the development of counter curves until a certain degree of corrective force is reached before which the original curve will give. Such a degree of force is usually intolerable if applied suddenly but gradual transformation of the curve to a certain point can be expected from lesser and tolerable degrees of direct force.

b. In part of the cases the correction may be maintained actively by muscle balance; such ability depends primarily on the development and training of the muscular apparatus of the back and on the general distribution of body weight in the trunk or in other words the general alignment; the latter again depends on the sufficiency of secondary contralateral offsetting or compensatory curves established in the neighboring sections of the spine.

In another part of the cases the spine can not be maintained by active muscle balance and the deformity progresses; here passive support of the spine becomes necessary by means of external or internal splinting. External splinting means braces which are not satisfactory as a permanent solution of the problem; internal splinting means operative fusion or arthrodesis of the spine; to this all cases must be relegated which cannot be definitely controlled by active muscle balance and inevitably progress in

deformity and in which no general or local contraindications to operation exist. But the fortune of the fused spine likewise depends on its general alignment. Spines which have been "realigned" by development of counter curves hold easier after fusion than spines with marked disalignment or overhang." In the latter fusion often breaks and pseudoarthrosis develops.

The practitioner who is seeking advice on the treatment of scoliosis is likely to meet up with a diversity of opinions among specialists which must be very disconcerting both to him and to his patient. The principal reason for this is because it is so uncertain what the particular case of scoliosis will do in the future if left to its own muscular safeguards, whether or not it will yield to manipulative correction and if so how much, whether or not if such correction is obtained it will become more difficult for the muscles to retain the position of the spine than it had been before.

Everything centers more or less upon the self corrective and self retaining power of the musculature. Thus the surgeon must first of all satisfy himself on these points. First is there a prospect of obtaining a restoration of the general body posture by developing compensatory curves and second is there a prospect of maintaining such recovery of posture by developing and training the muscles of the back in other words by active self correction. This cannot be settled at first glance during the initial examination. With the exception of severe paralytic and severe congenital cases in which we know that it is impossible to obtain active self correction because of lack of muscle material in one case and severe defects in anatomic construction in the other most cases and especially those of the static and habitual group will require careful observation for at least six months before it is decided whether a conservative or an operative program should be followed.

In the light of these viewpoints it is possible to plan a definite program for each patient.

1 Compensation Derotation Treatment.—The disalignment of the trunk against the pelvis and the overhang as it is called constitutes a state of decompensation of the spine as a whole. This must be corrected

first because in this state the deformity is progressive and there is no possibility of muscular control. Correction can be obtained only by establishment of adequate counter curves above and below the primary curve, i. e. in changing the C shaped curve into an S shaped or triple curve. This is done by passive mobilization together with massage and exercises. When this so called compensation is established or while it is being established attempts are also made to flatten the curves or eventually to straighten them out entirely if the degree of rigidity

Fig. 918.—Brace used in compensational derotation treatment.

permits. This is done by adding to the passive correction of the curve by side bending the so called derotation of the curves especially of the lumbar portion of the spine. This again is done by passive rotation of this portion of the spine through the pelvis. The muscle development must always keep step with the relaxation of the spine otherwise muscle control will be lost and the spine will collapse. A brace is worn between treatments to preserve muscle tone and to prevent fatigue.

The compensation-derotation treatment suffices in itself in a certain number of cases

namely cases of light or moderate habitual scoliosis and mild rachitis but in only a few of the congenital and practically none of the paralytic type

2 When it appears that results cannot be obtained by the compensation derotation method one must use more forcible means of correction with corrective casts applied in certain positions and in graduated steps. Two methods are to be recommended that of Galerazzi and that of Risser. Galerazzi is a corrective cast applied in a forward bent position with contralateral bending and rotation of the shoulder girdle and the sacro-lumbar portions of the spine. Its primary

Fig 219—Corrective cast in treatment of scoliosis front and back views

effect is in the sense of compensation curves leading according to the degree of rigidity to complete correction (conversion) of the primary curves in some cases. The Risser corrective cast is applied in a recumbent position and by means of a turn buckle arrangement one gradually obtains satisfactory compensation curves and in some few cases actual correction of the primary curve. All cases in which satisfactory compensation cannot be obtained by the so called compensation method should undergo cast correction. These include the more severe cases of the habitual type, the more severe rachitic scolioses, the older congenital deformities and late cases of paralysis which have progressed to marked structural deformity.

3 When it appears that compensatory correction by counter curves can be satisfactorily obtained by one of the methods previously mentioned but that correction cannot be maintained by active muscle balance that the spine is unstable and that progression of the deformity is therefore imminent it then becomes necessary to secure the spine by arthrodesis or a fusion operation provided there is no contraindication of a general nature to operative intervention. This type of correction is necessary in the majority of cases of paralytic and of congenital scoliosis and the more severe forms of the rachitic and habitual types. However there are a great number of exceptions some patients especially those with severe paralysis are poor operative risks in others the operative intervention may be balked by great technical difficulties for instance in cases of high cervicodorsal rachitic scoliosis. The operation of choice is a combination of the Hibbs and Albee procedure used in tuberculosis of the spine, the fusion by bone bridges and chips and reaming out of intervertebral articulations is further supported by longitudinal tibial or rib grafts placed on the arches into the concavity of the curve.

4 When it appears that neither correction nor improvement can be obtained to any acceptable degree by means of compensation curves and that the spine cannot maintain itself by active muscle force in whatever condition it may be either the patient should be placed in a brace for an indefinite time certainly until he attains full growth or an operation should be performed. In the latter case however the outlook for maintaining the spine in its proper position and preventing further collapse is not altogether certain as in many cases pseudarthrosis develops in the fused areas especially in the lumbodorsal region under the stress of the overhang of the body. As a rule the greater the general disalignment of the body the poorer the chance that the fusion will hold. The most severe and intractable forms of scoliosis of all types unfortunately a considerable percentage of all cases of scoliosis when they come under the physician's observation belong to this group.

This short outline of the treatment serves to emphasize the all importance of the earliest possible recognition and timely pro-

physiaxis of scoliosis. Until these vital facts have become generally appreciated there is not likely to be any real progress in the management of cases of scoliosis.

A STEADLER

ACUTE SUPPURATIVE ARTHRITIS

(Septic Arthritis Pyogenic Arthritis Pyemia of Joints Pyarthrosis)

Etiology.—Acute suppurative arthritis is an infection of a joint cavity and its constituent structures by pyogenic organisms. These organisms as a rule are either *Staphylococcus aureus* or one of the more common pathogenic streptococci; occasionally they are pneumococci, meningococci or other organisms.

In many instances a primary focus is not demonstrable but it is assumed that the focus or some other similar focus is the source. As a rule however the organism is carried in the blood stream to the joint from some region of acute infection elsewhere. In many cases this focus is a furuncle, a region of cellulitis or an ulcer. Meningococcal arthritis and pneumococcal arthritis as a rule occur in the course of diseases caused by *Neisseria intracellularis* (the cause of epidemic meningitis) or the *Diplococcus pneumoniae*. There are however isolated cases of pneumococcal arthritis not associated with pneumonia and reports have been made of cases in which meningococcal arthritis preceded the onset of definite epidemic meningitis. Any organ capable of causing infection in the human body may at times cause suppurative arthritis. This type of arthritis is a frequent complication in the course of septicaemia and of acute bacteraemia of various sorts.

There are cases in which direct extension takes place into a joint from a neighboring focus of infection such as a furuncle or a region of cellulitis near the knee joint. When wounds involve joints or when compound fractures occur joints may be invaded by infecting micro-organisms. Osteomyelitis particularly epiphysitis often may be complicated by suppurative arthritis.

Pathology.—The extent of the pathologic change depends on several factors: (1) the virulence of the causative micro-organism

(2) the resistance of the patient to that micro-organism and (3) the amount of pre-existing injury to a joint either by mechanical forces or disease before infection takes place.

Phemister demonstrated that cartilage may be rapidly destroyed when incubated in pus from pyogenic abscesses. The gross appearance of the cartilage when infection has developed in a joint varies somewhat with the stage and the severity of the infection. However fairly early the cartilage becomes almost the consistency of jelly, loses its pearly translucency and becomes opaque. In more severe cases it may be almost completely destroyed within two or three days. In less severe infections the process is much slower. Softening of the cartilage is of the greatest importance in determining the restoration of function. With softening of the cartilage begins the actual invasion of the substance of the cartilage by polymorphonuclear neutrophils and by the various cells engaged in repair following infections. With healing a scar tissue type of replacement takes place so that fibrocartilage is present in place of hyaline cartilage.

The pathologic changes in the synovial membrane are similar to those seen in any serous membrane that is exudation with clotting of fibrin on the surface of the membrane. The pouring out of polymorphonuclear leukocytes into the joint and into the membrane itself and the appearance of the usual elements of inflammatory tissue reaction follow.

The capsule is not involved in many cases. When it does become involved destruction of the capsule takes place with slow repair as in any ligamentous infection.

The bone adjacent to the joint may become involved and probably does become involved in all cases of severe infection of a joint. The intertrabecular spaces in the cancellous bone become filled with polymorphonuclear leukocytes and in the more severe cases actual necrotic portions may appear with subsequent sequestration and extension. In cases of acute epiphysitis with involvement of joints the entire epiphysis often becomes necrotic and eventually forms a sequestrum which must be removed.

Symptoms and Diagnosis.—The most common symptom of acute suppurative ar-

thrits is pain in the region of the involved joint. At first this pain may be noticed only on motion of the joint but as the disease progresses the pain becomes more severe and as the capsule of the joint is distended pain may be constant and usually is very severe. With the advance of symptoms any movement becomes exceedingly painful. Associated with pain is a limitation of movement and muscular spasm. Swelling usually follows and advances fairly rapidly until the capsule of the joint is fully distended. Redness may appear on the surface of the skin although in the deeper joints such as the hip joint this is by no means a constant symptom.

Besides the localized symptoms general reactions of more or less severity are usually seen. There is usually a general febrile reaction varying from slight to very severe. Malaise, chills, sweating and the other symptoms usually associated with febrile reaction may be noted.

The diagnosis of acute suppurative arthritis is in most instances fairly easy to make. Most of the joints of the body (the hip is a notable exception) are sufficiently superficial so that the localizing symptoms and signs are fairly easily detected and as a rule are easily recognized.

In diagnosing any case of acute suppurative arthritis one may expect to find swelling which obliterates the normal contours of the joint, increased local temperature, *increased fluid in the joint or thickening of the lining of the joint*. It is important to determine the presence of fluid. Muscular spasm causing limited movement is always present to some degree. There may be redness of the overlying skin, particularly in cases in which cellulitis exists. Deformity is usually present and is caused by the muscular spasm which holds the joint in a deformed position. Usually this position is the one of greatest comfort and is different for each joint. A leukocyte count is important. In suppurative arthritis the number will be elevated and the percentage of polymorphonuclear leukocytes will be definitely increased. From 10,000 to 20,000 leukocytes per cubic millimeter of blood are commonly found and much higher counts are often made. The other important diagnostic test is aspiration of the joint with removal of some of the fluid. A

culture of this fluid should always be made in order to determine the causative agent. With this point settled one often can decide on the course of treatment and may be able to predict the outcome more accurately than without this information.

Acute suppurative arthritis may be confused with several other conditions. One of these conditions is osteomyelitis involving the diaphyseal ends of bones; another is epiphysitis. Confusion is particularly likely to occur in those cases in which the infection lies so close to the joint that effusion takes place within it because of the irritation of the synovial membrane, but without actual bacterial invasion. Acute suppurative arthritis in its early stages may be confused with post-traumatic or infectious acute synovitis that is confined to one joint. In cases in which there is any uncertainty between these two diagnoses aspiration and examination of the joint fluid with culture if necessary will supply the necessary information. Hemarthrosis either as a result of trauma or as a postoperative complication may be very confusing at times. A hematoma often causes a sharp elevation of temperature but again the final diagnosis can be made by aspiration. Chronic infectious arthritis rarely is confused with acute suppurative arthritis. Rheumatic fever is sometimes difficult at first to distinguish from acute suppurative arthritis but the course of the two diseases is entirely different. Rheumatic fever spreads from joint to joint and there is no residual change in the joints. Occasionally bursitis, particularly very acute bursitis with marked swelling and pain may be difficult to distinguish from acute suppurative arthritis. As has already been indicated the signs of involvement of the hip are not so easily detected and a wide variety of conditions including osteomyelitis of the pelvis must be distinguished from acute suppurative arthritis of the hip. A pelvic or pros abscess with resulting flexion of the hip and occasionally appendiceal and renal infections may produce confusing pictures.

Prognosis.—The prognosis in acute suppurative arthritis is variable. Formerly in the more severe fulminating types of infection particularly those accompanying septicemia the danger to life was great. With the improved methods of chemotherapy the

danger to life has been greatly reduced. Without modern chemotherapy the condition must be regarded as serious in many cases some articular function is lost as a result of the disease. If function is severely impaired and slight pain persists on motion it is to be hoped that complete ankylosis eventually will result because this produces a stable useful limb provided ankylosis has been produced with the joint in the position of election. Following less severe types of infection normal function usually is restored.

Treatment.—Treatment today should start with the use of penicillin if available. Reports from all available sources indicate that if organisms sensitive to penicillin therapy are the causative agents good results will be obtained by the use of penicillin. Details as to administration of penicillin are not given here as they are available elsewhere in the volume. Lyons noted that suppurative arthritis responds dramatically. Penicillin may be injected directly into the joint or may be administered intravenously or intramuscularly. Dawson and Hobby suggested the injection of 10 000 units daily into the joint for three days.

If penicillin is not available sulfonamides may be used during the acute stages. One may inject an 0.8 per cent solution of sulfanilamide into a joint but it is not recommended that other types of sulfonamides be injected into a joint. Usually one depends on the oral administration alone. In cases in which chemotherapy has not been employed or in which the response to this type of therapy has been unsatisfactory surgical intervention is indicated if after several days illness a joint cavity is distended with purulent material. The type of drainage and the situations of incisions for drainage vary somewhat (Fig. 220). In general it may be said that incisions into joints should be made in the area where the joint lies closest to the skin. Usually in such areas the capsule is weakest and distention with fluid will be localized there. Thus in the knee joint the lateral pockets of the subquadriceps pouch will be the fullest and most easily drained. The same is true of the elbow where fullness will be detected on either side of the olecranon. In the ankle one of the following areas is most frequently used for approaching the joint: the region anterior to the fib-

ula the area between the anterior tibial tendon and the internal malleolus or the area posterior to the peroneal tendons. At the shoulder one finds a bulge posteriorly through the thinner portion of the deltoid muscle or between the deltoid and scapular border. The joint may be approached through this bulge or through an anterior incision splitting the deltoid muscle. The hip joint presents a different problem for it is more deeply placed. Many surgeons advocate the use of an anterior incision medial to the tensor fasciae femoris and lateral to the rectus femoris and sartorius. In most cases of acute suppurative arthritis of the hip joint however I believe a more satisfactory type of drainage will be obtained through Ober's incision—the fibers of the gluteus maximus muscle are split longitudinally and the subgluteal fat is opened. The surgeon should watch for the sciatic nerve at the medial angle of the wound should separate the gemelli inferior from the tendon of the obturator internus and should open the capsule of the joint by a crucial incision.

Once the incision into the capsule of the joint is made treatment varies somewhat with different surgeons. The majority agree that thorough lavage of the joint either with physiologic saline solution or with a mild antiseptic solution of some sort is best. Some believe that as soon as lavage is completed the joint may be closed. In general however the joint should be left open to allow free drainage. Drains should not be allowed to penetrate a joint if it is hoped to preserve the function of the joint and this applies particularly to counter drainage or to through and through drainage. Usually a drain introduced down to the joint and made either of rubber tube or petrolatum gauze gives the best results. Fixation of some sort is necessary in these cases for the inflamed surfaces of the joint will be kept activated if motion is not prevented for a few hours or a few days at least. Usually the best support for the various joints is furnished by the following devices: a molded plaster splint or a Thomas splint with Pearson attachment for the knee; Buck's extension for the hip; a right angled metal splint for the ankle; a cock up splint for the wrist; a right angled splint for the elbow and an arm plane splint for the shoulder.

Jones wrote "It is necessary to rest an arthritic joint until pain and inflammation have disappeared. Movements when commenced should be active not passive. Active movement will be limited by pain to an excursion that does not injure the delicate membranes of the inflamed joint. At the same time active movements develop the atrophied muscles a factor of greatest importance to the recovery of the normal function of a joint. Weight bearing must not be commenced until the softened joint cartilage has been restored to more or less normal

extreme cases with extensive destruction of joints and with no improvement under proper care amputation is indicated sometimes as a life saving measure and at other times as a measure of economy.

GNORRHEAL (NEISSERIAN) ARTHRITIS

Etiology and Pathology—Gonorrheal arthritis one of the complications most feared in cases of gonorrhea is in many respects similar to acute suppurative arthritis. It is a severe infection often polyarticular at first and later localizing in one joint. It is

Fig. 220—*a* Lines of incision on the ankle, knee and anterior aspect of the hip; *b* lines of incision on the elbow; *c* Obersteins' incision for posterior drainage of the hip; *d* Lines of incision for drainage of the shoulder.

consistency a process which takes weeks rather than days. Again the severity of the symptoms must be accepted as a guide. In the event of very severe infection of several days' duration in which it seems that ankylosis must result the surgeon should see to it that ankylosis in the most favorable position for whichever joint is involved is promoted.

After drainage is established one should continue chemotherapy until the patient is afebrile and evidence of subsidence of the local infection is clearly demonstrated. In

due to the Neisseria gonorrhoeae. In its pathology it is not unlike acute suppurative arthritis. Essentially the same sort of changes will be found in all the component parts of the joint. In the more severe cases injury to bone may not be so severe as in the extreme cases of pyogenic arthritis. The same rapid destruction of cartilage takes place in these cases however and the same severe synovial tissue reaction.

The incidence of gonorrheal arthritis as a complication of gonorrhea has been greatly reduced since the advent of

chemotherapy, and with penicillin therapy this complication apparently will be further reduced if not completely eradicated in cases in which gonorrheal urethritis is treated properly.

The onset almost always follows closely an episode of urethritis. Collings found in a study of 517 cases of gonorrheal arthritis that in 75 per cent of the cases involvement of joints developed within fifteen days of the urethral infection. Thomas found the incidence of arthritis in cases of gonorrheal infection to be between 2 and 3 per cent. The same author found that in 58 per cent of the cases involvement was polyarticular and in 42 per cent monoarticular. The joints involved and the number of cases in which they were involved were as follows: knee 58, hip 50, wrist 21, shoulder 19, pharyngeal joints 17, elbow 13, metatarsophalangeal joints 8, spine 8, metacarpophalangeal joints 8, sesamoid joints 1, temporomandibular joint 1 and sternoclavicular joint 1.

Involvement in gonorrheal arthritis is often multiple at first. Several joints may be involved one after another or several may be involved simultaneously in the latter type of case there is pain but very little swelling, redness or limitation of function. However one joint or at times two or more joints become much more severely involved there is marked swelling, severe pain, redness and increased quantity of fluid in the joint and deformity caused by muscular spasm. In addition to these local symptoms there is usually some general reaction although this is not so marked as a rule as that found in the presence of pyogenic infections.

Diagnosis.—The diagnosis in these cases usually is dependent on the discovery of the primary seat of infection. Acute arthritis complicating active gonorrhea is not necessarily gonorrheal arthritis; usually the arthritis is gonorrheal however. It is difficult in many cases to find the organism in the material aspirated from a joint probably because the organism remains embedded in the synovial membrane. In many cases the organism can be obtained by the use of cultures and identified by means of Gram's stain. Better methods of culture of the gonococcus particularly by the use of chocolate blood agar have demonstrated the presence

of the organism in a much higher percentage of cases. Infrequently, multiple infectious arthritis results from gonorrhea but the diagnosis is presumptive not positive.

In a few cases of gonorrheal arthritis gonorrheal septicemia develops and results fatally. As a rule however gonorrheal arthritis is not fatal. The function of joints often is lost because the swift destruction of the articular cartilage leaves ideal conditions for ankylosis. However if the progress of the infection can be stopped before destruction of the cartilage is complete restoration of the normal function of a joint can be obtained in many cases.

Treatment.—The treatment as in all cases of acute arthritis consists of rest and an attempt to eradicate the infection. The presence of gonorrheal arthritis in a case in which apparently adequate chemotherapy has been employed is an indication of failure of chemotherapy probably due to a resistant strain of *Neisseria gonorrhoeae*. In such cases penicillin therapy should be employed. Most of the sulfonamide-resistant types of gonorrheal infection will respond to penicillin. Ever therapy formerly helped in these cases but its need now seems doubtful in view of the apparently good results obtained with penicillin. To insure rest of the infected joints splints of aluminum, steel or plaster of paris may be used. At times pillows will suffice. In the very acute stage the joint may be kept in the position of greatest comfort but if ankylosis apparently will take place every effort should be made to have the joint in the position of maximal function. Wrapping the joint in cotton wool application of hikers and hot water bag, and the use of oil of wintergreen may add to the patient's comfort. Sedatives in fairly large doses may be necessary.

In combating the infection the first effort to be made is to rid the patient of the primary focus. This will be impossible in some cases but the attempt should be made. Aspiration of the joint relieves tension and often makes the patient more comfortable. Irrigation of the joint is often advisable.

With the subsidence of acute symptoms attention must be given to the restoration of the function of the joint. Active exercises are the most valuable because pain limits their use so that injury will not be caused

by them. At the same time they restore muscular strength. Joints which bear weight should not be used for several weeks or until the cartilaginous surfaces have become fairly well hardened. Function of joints which do not bear weight may be permitted earlier.

If ankylosis is apparently taking place and the original focus has been cleared up, manipulation may be tried after the acute symptoms have subsided. If ankylosis has taken place as a result of gonorrheal arthritis, arthroplasty is the only means of restoring motion. Such joints are usually very favorable for arthroplasty, but one must wait as a rule two years from the time of the original infection before attempting surgical treatment.

TYPHOIDAL ARTHRITIS

The relative infrequency of typhoid fever in most parts of this country now makes typhoidal arthritis a rarity. However its differential diagnosis in some cases must be considered. Osler wrote that there were 8 cases of typhoidal arthritis in a series of approximately 1500 cases of typhoid fever. Arthritis if it is to occur usually appears between the twenty-ninth and thirty-fifth days of typhoid fever, according to Crussade and Tardieu. Usually it presents the picture of a moderately severe suppurative arthritis and in some cases leads to ankylosis. In other cases the arthritis may be generalized and milder and recovery may supervene. Establishment of a diagnosis of typhoid fever is essential to a diagnosis of typhoidal arthritis and the bacillus should be recovered from the joint. Occasional cases of late typhoidal arthritis are reported. A positive Widal reaction performed on joint fluid is not sufficient evidence to support a diagnosis of typhoidal arthritis for the fluid usually will have the same reaction as the blood serum. Treatment in these cases depends on the severity of the symptoms but in general consists in fixation followed by massage and by exercises in the convalescent stages. Drainage will be necessary only in the most severe cases.

PAINFUL AFFECTIONS OF THE LOWER BACK

Anatomy.—The joints of the lower back are (1) the articular facets (2) the intervertebral disks and (3) the sacrospinous joints (Figs 201 and 202). The articular facets in the lumbar region face in the anteroposterior or sagittal plane. They are interlocked in such a way as to give freedom in flexion and extension and to allow a minimum amount of rotation. Because of this very limited play in rotation the lumbar portion of the spine is relatively stable and injuries occur chiefly in the positions of hyperflexion and hyperextension. The articular facets do not always face in the sagittal plane, sometimes being in an oblique and sometimes in a true frontal plane. This is particularly true of the facets between the fifth and first sacral vertebrae. Such an anatomical variation does not in itself give rise to symptoms but results in increased mobility in rotation and therefore predisposes to strain.

There are other anatomical variations which affect the function and stability of the region. The most common of these is the sacralization of the transverse process of the fifth lumbar vertebra (Fig 202). This may be either unilateral or bilateral. If unilateral it is particularly apt to render the function of the lumbosacral junction asymmetrical and therefore predisposes to strain.

Another quite common anatomical variation is spina bifida occulta—a lack of fusion

of the laminae of the neural arch (Fig 223). Such a variation is commonly associated with variations in the articular facets which

Fig 221.—Diagram showing the irregular congruous surfaces of the sacrospinous joint and the articular facets.

render the lumbosacral junction unstable and result in localized symptoms of strain.

Spondylolisthesis or a forward displacement of one vertebra on another occurs

Fig 222.—Lateral sacralization of the transverse process of the fifth lumbar vertebra.

more often at the lumbosacral junction than in any other region. It is commonly associated with a congenital defect in the ped-

icles of the fifth lumbar vertebra which allows the laminae and articular facets to remain in normal relation to the sacrum while the body of the fifth vertebra displaces forward. This condition may be very mild and accompanied only by local pain or it may be extreme and associated with symptoms due to pressure on the cauda equina.

The intervertebral disks are not true joints but perform the function of joints. They consist of three parts—cartilaginous disks above and below and the nucleus pulposus in the center which is surrounded by a third part, the annulus fibrosus. The structure of this disk is such as to allow compression as well as distraction in any direction.

The sacrospinous joints are true joints consisting of two irregular congruous joint sur-

Fig 223.—Sacrospinous joint.

faces covered by hyaline cartilage. They have a definite synovial membrane. The congruity of these joint surfaces tends to increase their stability (Fig 224) making up to some extent for the relatively inefficient ligamentous and muscular support. The oblique plane of the sacrospinous joints also adds to their stability (Fig 225). Because of this oblique muscular leverage rotating the ilium forward on the sacrum tends to put the joint surfaces into better apposition and cannot produce a ligamentous sprain. The iliopsoas muscle produces such leverage. Leverage rotating the ilium posteriorly on the sacrum tends to unlock the joint and therefore is effective in producing sprains. This type of leverage is produced by the hamstrings. The sacrospinous ligaments (Fig 224) are strong

superiorly, posteriorly and inferiorly; anteriorly, however, they are very weak and consist of a slight thickening of the periosteum.

which must be referred to when a diagnosis of lumbar or lumbosacral strain or sprain is being made (Fig. 225). The active or muscular support is the same for the spinal

Fig 224—The sacroiliac ligaments and the oblique plane of the sacroiliac joint

The supporting structures of the spinal joints are of two kinds passive (ligamentous) and active (muscular). The chief ligaments of the spine are the supraspinous, in-

terior and posterior longitudinal, and the capsular and interspinous. The position for the lumbar joints is also a stable position for the sacroiliac joints. The muscular groups that are of particular concern

Fig 225—Ligaments of the spine

terspinous, capsular, posterior longitudinal and anterior longitudinal. A clear mental picture of these supporting structures must be secured, since they are the structures

are the (1) erectores spinae, (2) abdominal, (3) gluteus maximus, (4) iliopsoas and (5) hamstring muscles.

1. Erectores spinae originate from the dor-

sum of the sacrum and posterior iliac crests and insert into the spine and posterior chest wall (Fig. 226). The function of this group of muscles is to resist gravity when the body is in the erect position and to assist in a return to the erect position from the forward bent position.

Fig. 226—Erector spinae, right side

2. The abdominal muscles (Fig. 227) represent extremely important support if normally controlled. When these muscles contract they approximate the pubes to the chest and in so doing tilt the pelvis into a more vertical and more stable position. This is particularly true if they are assisted by the gluteus maximus.

3. The gluteus maximus (Fig. 228) originates from the posterior ilium and lateral border of the sacrum and inserts into the greater trochanter and distal tibial band. When this muscle contracts it rotates the pelvis into a vertical plane. The cooperation of the abdominal muscles with the gluteus maximus constitutes a most important factor in maintaining a correct posture. With the pelvis in the vertical plane, the superior surface of the sacrum tends to become horizontal, and since this surface represents the founda-

tion of the spine, it should approximate the horizontal plane in order that the superstructure may be stable.

4. The iliopsoas muscles (Fig. 229) originate from the vertebral bodies, transverse processes and iliac fossae and insert into the region of the lesser trochanter of the femur. When they contract they approximate these two regions; consequently, if the femur is fixed they will tend to exaggerate the forward curve of the lumbar spine. This is an important point to keep in mind in the correction of faulty posture with an exaggerated lumbar curve; very commonly hyperextension exercises of the hips must be performed in order to stretch these muscles and overcome their vicious pull.

Fig. 227—Abdominal muscles.

5. The hamstring group (Fig. 229) originates from the ischium and inserts into the tibia and fibula. When these muscles contract they approximate these two regions, depressing the ischium and rotating the ilium posteriorly. This is the type of leverage to which the sacroiliac joints are particularly suscep-

tible and tight hamstrings predispose to sacroiliac sprain

Trauma—The *analysis of trauma* represents a valuable source of information which is frequently neglected. Injury to the spine—bony, ligamentous or muscular—results either from compression or from stretching

tract they diminish the flexion of the spine the spinous processes are approximated and the posterior ligaments are relaxed. The onset of pain indicative of injury during this act of lifting cannot be accounted for on the basis of a ligamentous sprain since these structures are becoming relaxed. Such pain can be accounted for on the basis of a muscular sprain. The erectores spine are actively contracting against the resistance of gravity and if the load is too heavy a muscular sprain results. Such a sprain practically always takes place at the attachment of the muscles to the periosteum of the sacrum and ilia and results in pain over these regions (Fig 231)

Fig 228—Gluteal muscles and hip joint

By analysis of the injury the structures exposed to either type of trauma are determined and the examination will consequently be directed toward these and therefore will be more intelligent

An analysis of an injury resulting from lifting is made as follows. In bending forward to lift an object a complex motion is performed. This consists of flexion of the spine and the tilting forward of the pelvis at the hips. What effect on the supporting structures does this motion have? As the spine becomes flexed the intervertebral disks are compressed anteriorly and the spinous processes are separated. As a result the supraspinous, interspinous and capsular ligaments are put on the stretch and by the tilting of the pelvis the hamstrings become taut (Fig 230). As the load is lifted the erectores spine contract and as they con-

Fig 229—Iliopectineus muscle

A sprain of the sacroiliac ligaments may result from a lifting injury. During the act of lifting the hamstrings with their origin from the ischial tuberosity and their attachment to the tibia and fibula are held taut to prevent the pelvis from tilting further forward consequently the leverage of the ham-

strings tends to rotate the ischium downward and the ilium posteriorly away from the sacrum. Since this is the particular type of leverage to which the sacroiliac joints are

subject it may occur also as an isolated injury from hyperextension or hyperflexion. The nature of the injury is such as to produce rupture of the annulus fibrosus allow-

Fig. 230—Analysis of injuries caused by lifting

susceptible a sprain of the sacroiliac ligaments secondary to the disalignment of this joint may result (Fig. 232). Lifting injuries, however, result in the majority of cases in muscular sprain of the erector spinae muscles.

Hyperextension injuries of course bring about an approximation of the spinous processes and the articular facets; consequently there may be a compression injury of the posterior ligaments or fracture of the spinous processes, laminae or articular facets (Fig. 233).

Sacroiliac sprains have been described as resulting from a lifting injury. Any action which involves contraction or tension of the hamstrings tends to rotate the ischium downward and forward and the ilium backward. A unilateral strain of this type is more effective than a bilateral strain and is well illustrated by the driving of a motor car (Fig. 234). Every time the clutch is put out or the brakes applied, especially by a small person with a short reach, the hamstrings are rendered taut and a vicious leverage is applied to the sacroiliac joints. This is a very frequent cause of sacroiliac strain.

Injury to the intervertebral disks may occur secondary to fractures of the vertebral

bodies. It may occur also as an isolated injury from hyperextension or hyperflexion. A ruptured annulus fibrosus sometimes protrudes into

Fig. 231—Diagram showing the distribution of pain due to muscle strain and muscle spasm

the spinal canal, producing localized pressure on the spinal nerves at the intervertebral foramina. Because of the tension of the spinal nerve, local and radiation pain results.

This condition has been recognized during the last few years only previous to that other clinical entity. As a matter of fact the clinical picture is difficult to differentiate

Fig 232—Diagram showing disalignment of the right sacroiliac joint

time operative findings were interpreted variously as indicating chondroma or fib

Fig 233—Diagram illustrating injuries caused by hyperextension

roma The clinical picture presented by this injury is as yet not diagnostic it adds an

etc. from that presented by strain or disease of the sacroiliac joint. It is associated with pain referred to the same regions as that due to some condition of the sacroiliac joint and the clinical findings are not such that at present a clear differentiation can be made between the two conditions.

There is no question that as additional work is done a definite amount of knowledge will be gained which will help in the diagnosis of so-called mysterious disorders of the back. The recognition of this clinical entity has led to the use of lumbar puncture as a routine in any case of pain in the back not relieved by conservative non-operative methods. In cases of injury to the intervertebral disks the localized irritation causes a rise in the total protein content of the spinal fluid. Unfortunately this rise is sometimes very slight or absent but in most cases it is above what is considered normal. The total protein content should be interpreted with respect to the age of the patient; the younger the patient the lower the total protein content should be.

The main point to be remembered about injuries to intervertebral disks is that they represent a new clinical entity, one that will account for some of the cases in which no diagnosis or an incorrect diagnosis has been made in the past.

Pain—It is possible to differentiate between three types of pain resulting from a lesion of the spine or sacroiliac joints: local pain, referred and radiation pain and pain due to muscle spasm.

A sacroiliac lesion is distributed over the gluteal region, posterior thigh, posterolateral calf and lateral border of the foot (Fig 238). This distribution of pain is commonly referred to as 'sciatica' and is present in the

Fig 234.—Diagram showing strain from motor driving.

Local pain is caused by localized swelling at the point of the lesion. *Referred pain* is pain referred along the peripheral distribution of the spinal nerve supplying innervation to the injured parts. The vertebral structures that is the ligaments, the periosteum and the synovia of the articular facets derive their innervation from the 'recurrent nerve' which is given off from each spinal

majority of cases of lesions of the sacroiliac joint (Fig 239).

Radiation pain results from tension of or pressure upon a nerve. A ruptured protruding intervertebral disk is a good example of

Fig 235.—Diagram showing the origin of the recurrent nerve (Quain's Anatomy).

nerve before the posterior primary division (Fig 235). Consequently lesions of the lumbar spine may be accompanied by pain referred to the anterior aspect of the thigh and leg (Fig 236). It is helpful to note that the five lumbar nerves supply innervation to the entire anterior aspect of the thigh and leg.

The sacroiliac ligaments derive their innervation from the first and second sacral nerves (Fig 237), hence referred pain from

Fig 236.—Diagram showing the distribution of the lumbar nerves to the anterior aspect of the lower extremity.

a condition accompanied by this type of pain.

Pain resulting from muscle spasm is never mentioned as a separate entity. It is usually included in the description of the primary pain resulting directly from the lesion. In response to a painful lesion protective mus-

cle spasm occurs as long as the local pain and sensitiveness persist muscle spasm per

Fig 232—Diagram showing the innervation of the sacral segments (Rudinger)

sists. Muscles continually contracting exert a continuous tension or pull on their peri-

Fig 233—Diagram showing the distribution of the first and second sacral nerves (Tinev and Riley)

osteal attachment giving rise to pain which the writer likes to refer to as "secondary

pain." In lumbar lesions there is this muscle spasm of the erector spinae and to some extent also of the glutei. In sacroiliac lesions also there is spasm of the same muscle groups so that secondary pain produced by such protective muscle spasm is the same in the two regions (Fig 231). This is one reason for the confusion that exists in the differential diagnosis between the two regions.

A careful history is of the utmost importance in localizing a lesion as well as in determining the structures involved, particularly a lesion involving the lower back.

Fig 234—Diagram showing the subjective distribution of pain in sacroiliac lesions ("scatica")

Lesions of this region always necessitate a differential diagnosis between those of the lumbar and lumbosacral regions and those of the sacroiliac joints. An accurate description of the onset of symptoms usually yields valuable information. If the lesion is due to some disease the history of any illness preceding the onset is important; if it is due to trauma then a detailed description of the injury must be obtained. An accurate description of the distribution of pain is particularly helpful in localizing a lesion.

Examination.—Inspection does not as a rule yield much information that is helpful

in making a differential diagnosis between lumbosacral and sacroiliac lesions. The patient's posture (Fig 240) should always be noted, since faulty posture predisposes to strain of both regions. The same is true of structural scoliosis—a mechanically unstable

Fig 240.—Showing faulty posture and correct posture

spine. The presence of muscle spasm and of lateral or anteroposterior deviation of the spine gives some information as to the acuteness of the condition but again does not differentiate between the two regions, since a temporary deformity of this type may be present in either. The presence of a kyphosis as a rule means disease or fracture with resulting deformity of one or more vertebral bodies. A prominence resembling a kyphosis is frequently seen at the dor-lumbar junction because of faulty posture; roentgenograms are sometimes required in order to rule out disease.

Palpation.—If a patient complains of a tender spot anywhere, one's first reaction is always to put a finger on it. This is an illogical method of approach because poking a sore spot makes it sorer, creates more muscle spasm and increases the difficulties of palpation. It is distinctly better to palpate

first those regions which are the least apt to give rise to pain. With this in mind one should systematically conduct palpation and do it in such a way that at all times one knows what anatomical structures are being palpated. Localized tenderness anywhere as a rule means a lesion of that particular region. This is true of the spine as well as of any other part of the body. In fact, tenderness is even more significant in the case of the spine, because the structures involved are so deep seated that they rarely give rise to any visible surface changes.

Diagrammatic representations of points of information regarding the lumbar, lumbosacral and sacroiliac regions are given in figure 241. Starting at the dor-lumbar junction, tenderness over the costovertebral angle may indicate the presence of some genitourinary lesion as well as injury to the transverse process of the first lumbar vertebra (Fig 241, 1). From this region one pro-

Fig 241.—Diagram showing points of palpation in the examination of lumbar, lumbosacral and sacroiliac disorders. (See text.)

ceeds downward, palpating the transverse processes of all the lumbar vertebrae as well as the overlying erector spinae muscles for tenderness. Tenderness at any one point may indicate fracture of the transverse process or a sprain of muscle attachments.

In palpating the spinous processes and interspinous ligaments (Fig 241 2) any deviation of the spinous processes in the anteroposterior or lateral plane must be particularly noted as such a deviation may indicate a fracture of the spinous processes or of the vertebral bodies or disuse of these structures. Tenderness of the interspinous ligaments is indicative of acute sprain or strain due to faulty posture.

Tenderness in the region of the articular facets (Fig 241 3) between the fifth lumbar and first sacral vertebrae is consistent with a lumbosacral sprain from a hyperflexion or hyperextension injury or from strain due to faulty posture. It may also be due to a muscular sprain since the erectors spinae cover the facets.

Pain or tenderness referable to the dorsum of the sacrum (Fig 241 4) is most commonly accounted for and the basis of an exaggerated lordosis with a postural and muscular strain. It may also be present secondary to protective muscle spasm accompanying an acute sprain either lumbar or sacroiliac.

The region of the iliac crests (Fig 241 5) may be tender because of muscle sprain of the origin of the iliocostalis muscle. Most commonly this point is used as a landmark in locating the spinous process of the fourth lumbar vertebra.

The iliolumbar angles (Fig 241 6). The transverse process of the fifth lumbar vertebra, the iliolumbar ligaments and the erectors spinae are the structures under the palpating finger. Tenderness at this point suggests possible fracture of the transverse process, strain of the iliolumbar ligaments due to faulty posture as well as an acute sprain of the same structure or of the erectors spinae. A unilateral sacralized transverse process of the fifth lumbar vertebra sometimes gives rise to tenderness and pain referable to the iliolumbar angle.

The posterior iliac crest and posterior superior spine (Fig 241 7) are chiefly important as anatomical landmarks but sometimes this region is sensitive in cases of muscle sprain or strain.

Spinous processes of the fifth lumbar and first sacral vertebrae (Fig 241 8). Tenderness is present here in cases of faulty posture and frequently in spina bifida occulta with

an ununited spinous process of the first sacral vertebra.

The region between the posterior superior spine and the posterior inferior spine (Fig 241 9). Here are located the inferior sacroiliac ligaments which are practically invariably sensitive in any lesion of the sacroiliac joint but particularly so in sacroiliac strain or sprain.

The sacrosciatic notch (Fig 241 10). It is worthwhile to palpate this region since it commonly shows tenderness whenever the inferior sacroiliac region is tender. The reason for this is that at this point the superior gluteal nerve after passing in front of the sacroiliac joint emerges and passes to its peripheral distribution. Any condition causing swelling in relation to the anterior aspect of the sacroiliac joint will secondarily involve the superior gluteal nerve and cause tenderness of its nerve trunk. Consequently tenderness at the sacrosciatic notch may be interpreted as evidence suggestive of a sacroiliac condition.

The sacrococcygeal junction (Fig 241 11). Tenderness of these ligaments must be interpreted as evidence of a sacrococcygeal injury—sprain, strain or fracture.

The sciatic nerve trunk (Fig 241 12). Tenderness in this region midway between the greater trochanter and ischial tuberosity at the level of the gluteal fold is of no value so far as a differential diagnosis is concerned. It represents simply sensitiveness of the sciatic nerve trunk which may accompany either lumbar or sacroiliac conditions. The logic of this statement is evident when it is recalled that the sciatic nerve is made up of the fourth and fifth lumbar and first second and third sacral nerves.

The foregoing outline gives an illustration of a systematic method of palpating the lumbar, lumbosacral and sacroiliac regions. Such palpation should be carried out with the patient in the different positions—standing, sitting and lying. Sometimes valuable information is obtained by palpation during the motions of flexion and extension.

Motions—In examining the mobility of a patient's spine there is one point that should be kept in mind. No information is gained by trying to find out *how much* the patient can be hurt. A great deal of information is gained by finding out *when* pain commences.

The patient therefore should be instructed to stop as soon as pain comes on if he is performing a motion actively; the examiner should stop if performing a passive test such as straight leg raising or passive lumbar flexion.

Motions if properly conducted should yield considerable evidence which will be helpful in the making of a differential diagnosis. This is true only if they are performed in the standing, sitting and lying positions. Forward bending standing (Fig. 242) when

structures under tension consequently the erector spinae remain taut preventing motion through the lumbar spine so that the motion takes place in the dorsal spine and in the hip joints, the pelvis pivoting forward.

Lateral bending is not particularly instructive as a differential sign but it may be confirmatory of other findings. If for instance a unilateral ligamentous or muscular sprain is suspected because of the type of injury and distribution of pain then bending to the opposite side will put the injured structures

Fig. 242—Diagram showing the characteristic forward bending in sacroiliac and lumbo-sacral disorders.

the spine is normal produces flattening and reversal of the lumbar curve, exaggerating the dorsal curve. How is this motion performed by a patient with a lesion of the sacroiliac or lumbo-sacral region? A patient with a sacroiliac condition bends forward in such a way as to avoid hamstring leverage transmitted through the pelvis and consequently flexes the lumbar spine to the limit of its elasticity but stops as soon as the pelvis tilts forward rendering the hamstrings taut. A patient with a lumbo-sacral condition if this condition involves the posterior ligaments, articular facets or erector spinae attempts to avoid putting the

on the stretch and consequently bring on or aggravate the pain.

Flexion while sitting (Fig. 243) normally can be performed so that the chest actually comes between the knees if these are kept separated. How is this motion performed in lumbo-sacral and sacroiliac conditions? A patient with a sacroiliac lesion frequently is able to bend freely, flexing the spine and tilting the pelvis forward; the reason for the free motion in the sitting position is of course the relaxation of the hamstrings caused by the flexed knees. A patient with a lumbo-sacral lesion bends forward in the same manner as he did standing since the lumbar struc-

tures, if sensitive, can move no more freely in the sitting than in the standing position; the curves of the spine therefore do not

as forward bending sitting, and in the case of a sacroiliac lesion, it can be performed as a rule quite freely, since the pelvis moves as

Flexion - Sitting

Fig 243—Diagram showing the characteristic forward bending in the sitting position in sacroiliac and lumbosacral disorders

change, and whatever motion takes place occurs at the hip joints.

Motions while reclining are exactly the same as when standing and sitting, with the

a whole and the hamstrings are relaxed. In lumbosacral conditions the examiner can easily flex the hips, but as soon as any leverage is transmitted to the lumbar spine which

Fig 244—Diagram showing the characteristic passive lumbar flexion in sacroiliac and lumbosacral disorders.

difference that in the lying position they are performed passively by the examiner, whereas in the standing position the patient performs them actively. Passive lumbar flexion (Fig. 244) then is exactly the same

tends to diminish the lordosis, pain comes on and muscle spasm prevents any actual flexion from taking place.

The test of straight leg raising (Fig. 245) is a reversal of forward bending standing.

By this test the hamstrings are put under tension passively, tending to rotate the ilium backward thereby subjecting the sacroiliac ligaments to strain and producing pain. Consequently in sacroiliac conditions this test is markedly limited on the affected side; it may also be limited on the opposite side in acute cases. The pain produced is always referred to the side complained of, no matter on which side the test is performed. In cases of lumbosacral strain straight leg raising may be restricted but never to the same extent as in sacroiliac conditions, and the restriction is the same on both sides. In cases of rupture of the intervertebral disk this test produces an increase in the radiation

spine without aggravation of pain, since this motion tends to render the iliopsoas muscle tense thereby rotating the ilium forward and relieving the sacroiliac joints from strain. If disease is present this is of course not true, since the tightening of the psoas muscle lateral to the sacroiliac joints will tend to put the diseased area under pressure. In patients with lumbosacral conditions this test may or may not be productive of pain. If there is a ligamentous sprain the posterior ligaments of the spine will tend to become relaxed and therefore no aggravation of pain will result. The opposite is true of a muscle sprain; hyperextension puts the muscular attachments to the periosteum under

Fig. 215.—Diagram illustrating the test of straight leg raising.

pain owing to the tension of the spinal nerve at the level of the rupture. The peripheral structures innervated by this spinal nerve are hypersensitive, consequently, any motion or test which puts them under tension causes aggravation of pain. The straight leg raising is therefore limited to a lower angle with the horizontal plane (commonly 25 or 30 degrees) than in any other spinal or sacroiliac condition.

The motion of hyperextension is best performed in the lying position; if the condition is at all acute it is very difficult indeed for the patient to extend the spine in the standing position. A patient with a sacroiliac condition is able to extend and hyperextend the

trunk and will therefore aggravate the pain. If the condition involves the articular facets there is aggravation of pain.

Röntgenologic Diagnosis.—By a careful examination the x rays are localized over the region suspected of injury or disease. Furthermore, by taking films in different positions, such as maximum flexion and maximum extension, one obtains additional information in regard to mobility. Very frequently roentgenograms taken in this way demonstrate lesions that are not demonstrable in the routine anteroposterior and lateral planes. Lumbar puncture followed by the injection of a radio-opaque substance such as lipiodol is of great help in diagnosing an l

muscular sprain adhesive strapping (Fig 247) is sufficient it should be applied over the attachments of the muscles involved in such a way as to diminish their function. In

or brace is therefore indicated. A belt (Fig 248) if properly constructed gives efficient support for both the lumbosacral and the sacroiliac region. It gives pressure over the

Fig 247—Diagram illustrating the proper application of adhesive strapping to lumbosacral and sacroiliac regions.

ligamentous sprains of the lumbar spine adhesive strapping is efficient at first if it is applied in a position of extension preventing flexion. Since ligamentous sprains require

gluteal regions tending to tilt the pelvis into a more vertical plane and at the same time lifts the lower abdomen. In other words it assists muscle groups on which the normal position of the pelvis is dependent. It also

Fig 248—Diagram illustrating the effect of a properly constructed belt for the treatment of lumbosacral and sacroiliac conditions.

protection for a period of from six to twelve weeks. Adhesive strapping is usually not adequate and the patient's skin will not as a rule stand it for this length of time. A belt

Fig 249—Diagram illustrating the leverage of a lumbar back brace.

affords a compression of the soft parts against the lateral aspects of the ilia thereby directly supporting the sacroiliac joints. A steel brace (Fig 249) is commonly used for the support of the lumbar spine and lumbosacral junction. It is effective in supporting

these regions but it does not efficiently protect the sacroiliac joints excepting in so far as it tends to render the pelvis more vertical.

Plaster casts should not be used in the treatment of sprains or strains. If properly applied they protect the joints involved but their effect is far reaching both physically and mentally. They produce muscle atrophy and joint stiffness; their effect on the patient's mind is decidedly unfavorable since they make the patient feel the injury must be very serious indeed to require such treatment. This is particularly true in industrial accident cases.

During the period of ambulatory treatment supportive measures should be supplemented by exercises. These at first consist chiefly in assuming corrective positions followed later by exercises which tend to correct faulty position and increase the mobility of the spinal joints.

Manipulative treatment is indicated only if the physical examination yields evidence of a misaligned sacroiliac joint. The principle of such manipulation is hyperextension of the spine and hip; this principle has already been applied in the position in which the patient was kept during recumbency. If this is not sufficient then active manipulation by the surgeon may be undertaken with or without an anesthetic. If rupture of the intervertebral disk is suspected manipulative treatment is contraindicated since it may result in further protrusion of the ruptured portion of the disk and permanent harm to the crura equina or spinal nerve. In such cases prolonged support in neutral position or in slight flexion is indicated. If conservative measures fail operative removal of the ruptured portion of the disk with or without fusion is indicated.

Throughout the acute stage drugs are in

articular facets or the spinous processes. When such underlying conditions are present operative treatment is advisable in order to achieve permanent relief. These operative measures consist in fusion of vertebrae of one type or another of the lumbar and lumbosacral regions. By a fusion operation is meant either a massive tibial bone graft by the method of Allee or a Hibbs fusion operation or some modification of these two principal methods. The object of such operative treatment is to eliminate motion in joints which are mechanically imperfect.

In cases of chronic sacroiliac strain there need not be an anatomical variation. An acute sprain of this joint very frequently means a permanent weakening of the supporting structures so that even though the acute symptoms may be temporarily relieved a recurrence is brought about as soon as the patient attempts to resume his normal activities. By such recurring strain damage is done not only to the supporting structures but also to the hyaline cartilage covering the joint surfaces. Consequently the congruous surfaces no longer lock as they do normally. To overcome such instability of the sacroiliac joint fusion operations of various sorts are again indicated.

The underlying principle in fusion operations of the sacroiliac joint is anchorage of the ilium to the sacrum. This can be brought about either by extra articular or intra articular bone grafts. The extra articular fusions aim to produce bony bridging between the posterior iliac crest and the dorsum of the sacrum; an intra articular fusion operation produces bony bridging through the center of the joint.

M. A. SMITH, PETERSEN

trophic arthritis degenerates arthritis non-ankylosans arthritis osteoarthritis osteoarthritis deformans arthritis deformans senilis arthritis in alium coxae senilis indolens progressive osteoarthritis Type II (Fib) Type I (don't know—Fisher) monarticular type menopausal as applied to the spine osteoarthritis hereditary traumatic kyphosis von Reckterew type, arthritis deformans

Definition—Chronic arthritis is a widespread low grade chronic progressive inflammation of doubtful etiology involving the tissues and structures of one or more joints. The chronic involvements of joints arising from the invasion of specific organisms such as the tubercle bacillus, the gonococcus, the pneumococcus or similar organisms are not included under the term chronic arthritis.

Chronic arthritis is the oldest disease in both man and animal of which we have skeletal evidence. It is widespread throughout the animal kingdom and is present in practically all parts of the world. Probably no other disease produces such generalized disability and consequent economic loss.

By general acceptance chronic arthritis has been divided into two main subdivisions: (a) the atrophic type and (b) the hypertrophic type.

Differentiation between the two types of chronic arthritis. The atrophic type is an infectious involvement of one or more joints occurring in the earlier decades of life. It is marked by swelling of the soft parts surrounding the joint and causing it to assume the configuration of a spindle; this is associated with pain and limitation of motion. The limitation of joint motion is due first to muscle spasm but later to the adhesions developed within the joint. Fluid is usually present within the joint space. Ankylosis of the affected joint is the common outcome of the infectious inflammation. Histologically the atrophic type is marked by an invasion into the synovial membrane and villi of small round cells and occasionally of neutrophils together with the growth of a pannus over the articular surface of the cartilage.

The hypertrophic type is a joint inflammation of unknown etiology; it is more common in the later decades of life and more frequent in females. With the exception of the middle and terminal finger joints, the larger joints of the body are more often involved than the smaller ones. The affected

joint becomes distorted and mechanically damaged but does not become ankylosed excepting in the spine. Rarely is there marked limitation of motion, painful swelling or fluid within the joint cavity. The chief histologic change is that of irregular overgrowth of new bone especially at the margin of the capsule insertion. The changes are a combination of a serious degeneration with those of a low grade inflammation.

Etiology—In the atrophic type of chronic arthritis it is generally regarded that the disease is due to infection. Despite a great amount of detailed study, the isolation of a specific organism has proved to be impossible for the condition has failed. Many investigators have isolated from the blood stream joint cavities or other sites various streptococci strains which they regard as causative. In no case have these strains been substantiated. The specific organism or virus responsible for atrophic arthritis remains to be isolated.

The basis on which the belief in the infectious origin of this type of arthritis is founded lies in the clinical course of the disease, the concomitant occurrence of foci of infection in other parts of the body and in the pathology of the joint involvement. When considered these factors permit of no other interpretation.

The rapidity with which the atrophic type developed in young Marines subjected to jungle combat was most startling. Four to six weeks was sufficient time to permit extensive joint involvement especially of the spine. It was my impression that extreme fatigue was the most important predisposing factor.

The causative agent of the hypertrophic type of chronic arthritis is unknown. An infectious origin is unlikely. Because there frequently occurs in patients suffering with this disease a faulty digestion of food products and distinct abnormalities of intestinal function, it is believed that the absorbed products of incomplete digestion may be largely responsible. The frequency with which diminished local circulation is found to occur in this type leads to the belief that such a phenomenon may play an important causative role. Experimental evidence adds weight to the significance of faulty circulation as a factor. Insufficient stress has been

laid on the role of local joint trauma as a predisposing factor. Such trauma need not be excessive but may comprise merely the stresses and strains of normal life on inferior joint structures. Experimental work has shown that (1) articular cartilage cells diminish numerically with advancing age, (2) the nuclear volume does not lessen with aging, (3) old cartilage cells split glucose as readily as young ones and (4) the ability of old cells to consume oxygen is far less than that of young cells. (5) It is suggested that the degenerative changes of articular cartilage which accompany aging are related to (a) a diminution in the number of the cartilage cells incident to age and (b) the inability of the old cartilage cell to breathe adequately. The factors of mature age and increased body weight of the persons who suffer from this type of arthritis give added significance to the importance of trauma as a deciding factor.

Pathology of Chronic Arthritis—Atrophic Type—HISTOLOGIC CHANGES IN THE SYNOVIAL MEMBRANE—There is a well defined numerical increase and hypertrophy of the synovial villi. All are in a state of inflammation. In some the synovial fringes are necrotic in other hemorrhagic. About the blood vessels of the synovial membrane and villi are found numerous massed aggregations of small round cells. The villi during the early stages are highly vascular but later their fringes become fibrotic or necrotic as the lumen of their vessels becomes obliterated.

CAPSULAR CHANGES—Fibrous bands are formed early by the organization of the inflammatory exudate in the capsule and synovial membrane. These shorten and produce contractures of the part. Calcification of the bands ensues and the joint becomes fixed.

ARTICULAR CARTILAGE CHANGES—These occur early in the disease but are usually subsequent to the changes in the synovial membrane. A most important and characteristic feature is the development and gradual inward growth of a pannus on the joint surface of the articular cartilage. Composed of a highly vascular tissue the pannus resembles granulation tissue. The deeper layers of the pannus invade the articular cartilage alter its structure and destroy its integrity. In this manner the original surface

of the articular cartilage is gradually replaced by a layer of connective tissue which not infrequently contains nodular areas of newly formed cartilage.

EPIPHYSAL BONE CHANGES—In the cancellous spaces of the epiphysis and in the subarticular bony lamella there occurs connective tissue proliferation associated with the formation of new blood vessels and accompanied in many cases by invasion of lymphoid and plasma cells. There is an increase of osteoblasts; these attack the bony trabeculae and by resorptive activity enlarge the cancellous spaces. New bone is soon laid down. Processes of vascular connective tissue preceded by osteoblasts penetrate the zone of provisional calcification. New subarticular bone is formed. From its under surface the articular cartilage is attacked and destroyed in circumscribed areas by invading connective tissue. The cartilage cells of the articular cartilage are destroyed and replaced by connective tissue, new cartilage and bone. This upward invasion meets with the downward growth of the pannus which has formed on the articular surface of the cartilage. The process is neither regular nor uniform. The articular cartilage is destroyed in patches through degeneration and as it is replaced by fibrotic elements there is produced an uneven irregular bony articular surface. Even in the earlier stages owing to the absorption of calcium salts an atrophy of the bone is seen roentgenographically.

Hypertrophic Type—SYNOVIAL MEMBRANE CHANGES—These usually are not apparent until lifting of the articular margin has occurred. At the point of lifting the synovial membrane is thickened and there is proliferation and enlargement of pre-existing villi and formation of new villous processes. The synovial fringes retain vascularity late into the disease. The involvement of the synovial structure is not as extensive as in the atrophic type.

CAPSULE AND INTRA ARTICULAR STRUCTURE CHANGES—In a remarkable manner the joint capsule migrates to accommodate itself to the altered contours of the bones in those cases in which erosion and shortening of the articular bone ends occur. The intra articular menisci or semilunar cartilages degenerate and disappear.

ARTICULAR CARTILAGE CHANGES—The first changes are seen in the central poorly nourished portion of the articular cartilage. The semitranslucent white cartilage becomes yellow and opaque. It becomes pitted and fibrillated, frequently the matrix splits longitudinally. Erosion and pitting continue and at the bottom of the pits denuded bone may be seen.

Epiarticular echondroses appear as rounded elevations with a smooth surface and give an irregular granular appearance to the cartilage. They are caused by the invasion of the deeper layers of the articular cartilage by vascular ingrowths of osteoblasts engaged in forming new bone or to ossification occurring in the center of the articular cartilage which has previously undergone local hyperplasia. As the condition continues the cartilage disappears revealing bone.

LATERAL PORTION OF ARTICULAR CARTILAGE—The more viable and vascular lateral portion hypertrophies and projecting laterally produces lipping at the articular margins. This formation of new cartilage at the margin succeeds the degenerative changes of the central portion. The rhinodrophytes so formed ossify through the invasion of osteoblasts from the neighboring bone and become osteophytes.

FIBROUS BONE CHANGES—Before the articular cartilage has disappeared the underlying bone is found to be thickened and denser than normal. Occasionally the periosteum near the articular margin proliferates and forms osteophytes (Heberden's nodes). Beneath the dense bone the cancellous spaces are unusually open and fat filled. Cysts may be found in inclusion masses of cartilage beneath the sclerotic zone. The exposed bone surfaces undergo burnation and become polished. Owing to the atrophic processes going on in the bone immediately beneath the articular surface considerable alteration in shape of the articular surface takes place as a result of pressure. Absorption is most marked where pressure is greatest. Actual shortening of the bone may take place.

Symptomatology—Atrophic Type—Since it usually attacks the thin platy undernourished young adult the atrophic type of chronic arthritis involves most frequently

the smaller joints. The early symptoms are those of local stiffness, pain, tenderness, swelling and temperature change. These vary greatly in degree. Stiffness may be evidenced merely by the feeling of lack of freedom of joint motion or by the actual limitation of motion by muscle spasm. Limitation of chest expansion is one of the earliest signs of involvement of the spine. Pain may be absent when the joint is at rest or constant and of excruciating severity. Tenderness may be elicited with difficulty or produced by the weight of the bed clothing. Swelling may not be visible but can be detected by palpation. The joint outline becomes misshapen frequently there is marked distention of the capsule by fluid within the joint cavity. Heat of the part is present in some degree. Later symptoms are but progressions and regressions of the earlier symptoms. Pain is usually less severe. Muscle weakness with local and peripherally spreading atrophy is most common and characteristic and is frequently of such severity as to be completely disabling. The limitation of motion is progressive. Deformities: Flexion contracture of the part usually occurs and frequently despite intelligent attempts at prevention. The resulting deformation is pitiful in the extreme. Cutaneous manifestation: Vasoconstriction and inflammatory thickening of the peripheral phalangeal articular and capillaries cause the nails to become discolored and brittle. Numerous dermatoses occur secondary to the disease and are resistant to treatment.

Hypertrophic Type—**Early Symptoms**—Stiffness is far less marked than in the atrophic form. Muscle spasm is frequently absent. The range of joint motion is usually slightly decreased. Pain is absent when the joint is at rest and is usually not elicited when the joint is moved through its free range. Motion beyond the range of limitation may produce pain as may weight bearing. Palpation of the lateral margin of the joint elicits local areas of tenderness, this is particularly true of Heberden's nodes. Synovial involvement is manifested early by the ease with which backache is brought on by bending and the lifting of light weights. Pain referred along the intercostal or lumbar roots (intercostal neuralgia) is an early manifestation of spinal involvement. Swelling

ing of the larger joints is usually absent, but swelling of the smaller joints, especially during the development of Heberden's nodes on the finger is common. *Temperature changes* are usually absent excepting in the area of the finger joints. **LATE SYMPTOMS** Pain is only present after overactivity, it is more pronounced in the hip joint and over the exostoses than elsewhere. *Muscle weakness and atrophy* are absent. *Limitation of motion* is progressive because of the distortion of the joints by bony overgrowth. Neither fibrous nor bony ankylosis occurs except in the spine. *Deformities* are present in the nature of local distortion of the joint contour, but flexion contractures are not common excepting in the fingers. Here they are due to bony overgrowth rather than to fibrotic contracture, as in the atrophic type.

Diagnosis—The diagnosis is based on the symptomatology and physical findings.

Atrophic Type—**ROENTGENOLOGIC EXAMINATIONS** in the earlier stages are frequently considered negative by the inexperienced, but careful examination will show a degree of decalcification with lace-like trabeculation. The perirarticular structures are found to be more dense and swollen than normal and an increase of the joint cleft can usually be demonstrated. As the disease advances, atrophy increases and evidence of ankylosis is seen together with changes in the contour of the epiphyses.

LABORATORY FINDINGS—The basal metabolic rate is lower than normal. Mild secondary anemia is present and is frequently associated with mild leukocytosis. The blood pressure is low. The body temperature is subnormal or slightly elevated. During the active stage of the disease the erythrocyte sedimentation rate is above normal. Cecil and others have found that the blood serum agglutinates in a high titer various strains of hemolytic streptococci.

Hypertrophic Type—**ROENTGENOLOGIC EXAMINATION** early shows the presence of marginal "hopping" exostosis and irregular bone hypertrophy. There is absence of decalcification. The bone overgrowth and consequent distortion of the joint frequently become most excessive.

LABORATORY FINDINGS—The various routine and special examinations fail to give any characteristic findings.

Prognosis—As far as the occurrence of disability, deformity and invalidism is concerned the prognosis in the atrophic type is extremely poor and will remain so until a truly specific therapy is evolved. The present state of therapy does not warrant an optimistic outlook. Much can be accomplished as regards prevention, amelioration and control of the more severe deformities, but the disease, when viewed in its entirety, is a depressing one.

The hypertrophic type presents a less somber prognosis. It is more amenable to treatment and chiefly because of the grossness of its pathology, lends itself more suitably to the surgical and mechanical correction of distortions.

Treatment—The only hope for success in the treatment of chronic arthritis lies in thoroughness and persistence. There is no specific therapy. All branches of medicine must be employed, surgical treatment must be resorted to and above all the morale of the patient must be supported.

A most exact and detailed history should first be obtained, from such a history will be elicited many valuable suggestions as to treatment. By means of a physical examination one should strive first to estimate the bodily efficiency of the patient and to detect the presence of possible foci of infection. An orthopedic examination is made to determine the type of body build, posture, muscle tone, abnormal lines of weight bearing and the exact condition of the various joints. Nothing should be taken for granted, nothing overlooked. The smallest abnormality of structure or function should be detected and correction attempted.

The role of foci of infection in chronic arthritis has become insecure. To them can no longer be assigned the full responsibility for the disease and their removal is not always indicated nor attended by relief. Should the existence of foci of infection be proved and should the general condition of the patient warrant assuming the risk attendant on removal, then eradication is indicated. Most commonly, pyorrhea, an apical dental abscess, infected sinuses or tonsils or an infected gallbladder or appendix constitutes the focus of infection. The presence of cystitis, pyelitis, cervicitis, prostatitis or vesiculitis must not be overlooked. The large

intestine is frequently a veritable cesspool of pathogenic organisms. Though foci of infection may be located early, it is not always wise to remove them immediately, safer progress is made if the general health of the patient is first improved.

The patient suffering from chronic arthritis of either type is usually below par physically and is fatigued both mentally and physically. Relief of fatigue is the first step, the patient is put to bed for several weeks. The bed should either be boarded or should have a hard mattress. For several half hour periods daily the patient should lie on his back with a small pillow beneath the mid thoracic portion of the spine. Such a procedure aids in overcoming the existent hyperextension of the spine, increases the costal angle permitting greater ease in breathing and a consequently improved general circulation through more efficient heart action. The continued rest in bed relieves muscle spasm and permits relaxation of abnormal spinal and sacral joint alignment.

Pain should be controlled from the beginning by the adequate use of salicylates, but the relief of pain must not be considered an indicative of cure.

Diet is of the utmost importance. Patients with the atrophic type of arthritis are usually undernourished; those with the hypertrophic form are usually overweight. The diet of each form should be designed to correct the salient abnormality. In either case an adequate supply of vitamins B and D should be given together with a fair amount of bulky food of relatively low caloric value.

Physical therapy is of the greatest value in the treatment of chronic arthritis. The measures most used are local and general massage, colonic lavage, radiant heat and diathermy, immersion baths, passive and active motion and exercises.

The distended sluggish colon of the arthritic patient cannot but be benefited by colonic massage augmented by occasional colonic lavages.

Very gentle massage of the structures about the affected joints should be given preceded by radiant heat. Massage and heat properly used will improve the deficient local circulation of a part and thus reduce materially the local swelling and edema. Vigorous local massage is contraindicated.

General massage following ultraviolet irradiation or exposure of the body to infra red rays should be used to improve the muscle tone and the general circulation. Passive motion of an affected part should not be permitted until the local resistance has been improved through the judicious use of massage. When started motion should be slow and never carried to the limits of the motion range of the joint. When the patient has been taught his limitations, active motion of the part may be permitted but never to the point of fatigue. Exercises are prescribed to bring into use all the muscles of the body. great care must be given to the choice of the exercises and to the manner in which they are performed. Fatigue must be avoided.

Immersion baths of heated hypertonic salt solution are beneficial. Local contrast temperature sprays stimulate the local capillary circulation by producing local vasodilatation which persists for some time.

During the past ten years the author has had gratifying results from the intravenous treatment of the less severe forms of hypertrophic arthritis with colloidal sulfur. The clinical results contraindicate the adverse experimental data on the properties of this substance.

Vaccines—The arbitrary use of vaccines is to be discontinued.

Chemotherapy—The sulfonamides have a limited value in the treatment of the atrophic type. Penicillin has given remarkable results in a very small series of cases of the atrophic type. Its further use is indicated on an empiric basis.

Operative Treatment—Operative treatment includes both mechanical and operative measures. The former consists of the application of supportive bandages, braces and corsets as well as the insertion of pads, wedges and lifts in the shoes. These measures are designed to correct faulty posture, to limit the joint motion or to support weakened muscles and relaxed ligaments.

Operative measures may be used to correct existing deformities. Such procedures comprise lengthening of contracted tendons and joint capsules to overcome flexion contractures, removal in whole or part of the synovial membrane of a joint (synovectomy), severance of ankylosed joints and plastic repair of the same (arthroplasty).

fusion of joints in positions of election (arthrodesis) and such other reparative or reconstructive procedures as the individual case may demand. Much benefit has been obtained by the author in mobilizing knee joints by excision of the patella and synovium. The wider use of operative measures would lessen materially the number of arthritic derelicts.

SOME DISEASES OF BONE THAT ARE NOT INFECTIOUS IN ORIGIN

INFANTILE SCURVY

Scurvy is a generalized condition which is due to an insufficient amount of vitamin C in the diet. Most of the cases occur in the second half of the first year of life, although occasional cases are seen in older infants and in young children. It is characterized by changes in the gums which become swollen and purplish. In severe cases bullae filled with serosanguineous fluid may develop on the gums and if erupted teeth are present these may become loosened. In addition to the changes in the gums, the long bones especially the femora and humeri may be the site of subperiosteal hemorrhages. As the disease subsides under appropriate treatment the gums tend to return to normal but the subperiosteal hematomas may become calcified.

Symptoms—The onset of the disease is gradual. The infant is pale, does not gain weight, is irritable, tends to cry when lifted or moved or when the extremities are palpated as though these extremities were tender and tends to lie with the lower limbs extended and externally rotated as though they were paralyzed. In such an infant more than six months of age and less than two years of age one should suspect scurvy and inquire concerning his diet. Areas of swelling and purplish coloration on the gums confirm the diagnosis.

Treatment—The treatment consists of supplying an adequate amount of vitamin C. This is best obtained from oranges, lemons or tomato juice which should be given in doses of 3 teaspoonfuls three times a day or the concentrated vitamin C may be used. While frank adult scurvy is almost unknown there is evidence that subclinical scurvy may occur in adults as a result of avitaminosis. For this reason surgeons who treat patients with chronic disease should consider their diet and see that it includes an adequate amount of ordinary foods and vitamins.

RICKETS

Rickets is a condition of early childhood which is characterized by weakness of the muscles and softening of the bones. It is due to faulty calcium metabolism which is manifested by failure in the absorption of calcium from the digestive tract. Since the absorption of an adequate amount of calcium depends on the ingestion of calcium and phosphorus in the food and also on an adequate supply of vitamin D, rickets may be produced experimentally by eliminating any of these substances. In the temperate zones rickets is one of the most common diseases of childhood. It is said that about 90 per cent of the children of the poorer classes in large cities are at some time affected with rickets. This does not mean that 90 per cent of the children have rickets to such a degree that their bones are deformed, but that a careful laboratory, clinical and roentgenologic examination of these children would reveal abnormalities which would come under the classification of rickets.

Pathology—Pathologically the disease is characterized by the production of osteoid tissue which fails to calcify. Bone resorption proceeds normally or perhaps more rapidly than normal and new organic bone is produced but this is not impregnated with calcium salts and the resultant osteoid tissue may be bent or deformed from gravity or muscle pull. As the rickets heals the osteoid bone is calcified in its abnormal shape and thus may result in a permanent deformity. In the roentgenogram the earliest change in rickets is seen as an irregularity and increased radiability of the epiphyseal line. As the disease advances the epiphyseal portion

of the bone broadens so that the diaphysis appears to be shaved out at its epiphyseal end and the zone of rarefaction becomes wider. As the disease heals, calcium is deposited in this broadened rarefied epiphyseal region and is visible in roentgenograms.

Symptoms.—Rickets is insidious in its onset. The child tends to be lethargic, indolent and inactive. There is frequently no appearance of malnutrition and the child may be quite fat. He tends to sit with his back bowed forward and part of the body weight supported by the arms. The forehead is prominent and the fontanelles are slow in closing. As the disease advances, the wrists, knees and ankles become enlarged and the rachitic rosary, which is due to thickening of the ribs at the costochondral junction, may be evident. With further progress of the disease the spine may be curved forward in a long gradual kyphosis. The abdomen tends to become protuberant, the chest tends to become flat at the sides (Harrison's groove) and deformities develop in the long bones. These deformities are partly due to gravity and partly due to muscle pull. The most common is an outward bowing of the entire lower extremity so that the deformity of genu varum—bow legs—is produced. The next most common deformity is anterior bow legs in which the tibia is bowed forward. Rachitic knock knees are also fairly common. Rather rare deformities are coxa vara in which the neck of the femur is bent downward and deformities of the arm and forearm.

Treatment.—For the purpose of treatment clinical rickets may be divided into medical and surgical rickets. Medical rickets including those cases in which permanent deformities requiring surgical treatment have not developed but in which there is an indication for the regulation of the diet with the administration of adequate amounts of calcium usually in milk and adequate amounts of vitamin D usually in sunlight, cod liver oil, haliver oil or cholesterol. There are many children with mild deformities especially mild bow legs or knock knee. In the great majority of these cases the mild deformities will yield to conservative treatment (properly fitting shoes, manipulation and postural exercises or braces). Severe deformities which persist some year after the

rickets has healed should be corrected by osteoclasis or osteotomies. In osteoclasis the bone is broken by means of an osteoclast. This is advantageous because the operation is bloodless, requires a relatively short anesthetic and in addition to the breaking of the bone the soft tissues are stretched so that the deformity may be more easily corrected and held corrected in plaster. Osteotomy has the advantage that the correction can be made more exact (usually a wedge can be removed at the apex of the curve) but it has the disadvantage that there is always some danger of infection and that even after the bone is cut through there may be some difficulty in the correction of the deformity because of contracture of the soft tissues.

In addition to the deformities in the long bones, children who have had rickets are apt to have flat feet. These may be amenable to correction by means of exercises and properly fitting shoes. On the other hand in older children there may be considerable deformity in the bones of the foot so that in spite of exercises and proper shoes the patient will remain flat footed unless an operation is performed for the correction of the deformity. This can be done and a foot with a good arch can be secured. Pathologic fractures may occur in florid rickets and should be treated adequately until the diet corrected.

OSTEOMALACIA

Osteomalacia is a condition which occurs in adult life. It is due to a deficiency of calcium and of vitamin D in the diet. It is principally seen in women of the Far East, who subsist on a low calcium diet, who stay indoors most of the time and in whom pregnancy causes a marked drain on the calcium in the body. Other cases known as human osteomalacia were seen in large numbers in the central European countries during and after the first World War when the inhabitants of these countries subsisted on a diet low in calcium. The condition may be suspected in patients who complain of vague rheumatic like pains in the back and in the extremities. Rarely does the disease proceed to a point where pathologic fractures or deformities from bending bones are evident. In such a patient roentgenograms of the long bones show marked rarefaction al

though of course none of the changes of rickets since the epiphyseal lines have disappeared

The treatment consists of supplying a high calcium diet plus an ample amount of vitamin D given as cod liver oil or viosterol. In senile osteomalacia treatment with follicular hormone is added to the high calcium and vitamin D regime for women.

PAGET'S DISEASE

(*Osteitis Deformans*)

Paget's disease is a generalized disease of adult bone which is characterized by enlargement and softening. The etiology is unknown and though hyperactivity of the parathyroid has recently been suggested observations on calcium metabolism have not supported this theory. The pathologic changes consist of the transformation of the blood forming elements of the bone marrow into vascular connective tissue, the irregular resorption of the bone and the production of new bone which is largely subperiosteal. It is characteristic of the disease that the production of new bone, bone resorption and replacement by vascular granulation tissue go on side by side.

Symptoms.—Paget's disease occurs in middle adult life and is rarely seen before the age of thirty. The onset is insidious; the condition may progress very slowly and may be present over a period of years before any clinical symptoms arise. The bones most commonly affected are the tibia, skull, femur, pelvis and spine. As the disease progresses the affected bones become thickened and softened. With the softening of the bones deformities occur so that the tibia tends to be bowed forward and the femur outward while the spine develops a kyphosis; thus the patient loses in height and at the same time the head enlarges so that he must wear a larger hat. In some cases patients complain of rheumatic pains in the back, hips and lower extremities. They also complain of weakness and inability to lift or carry weights. In certain instances the pain may be so severe that a sedative is indicated for relief.

On physical examination enlargement and bowing of the bones may be noted. The af-

fected bones may be tender and there is a definite increase in the local temperature.

Diagnosis.—The diagnosis is confirmed by roentgenograms and many cases which cannot be diagnosed clinically are first suspected after the x-ray examination. Roentgenologically the affected bones have lost their normal structure and present irregular areas of increased density and of rarefaction. There is a definite tendency for some bones to be coarsely striated as though certain elements have been destroyed while other have become more dense than normal. On the surface of the bone there is evidence of the formation of new bone which has a cotton wool or fuzzy appearance and which produces an increase in the diameter of the bone. This is particularly true of the skull which may be markedly thickened. Since the bones are much weakened by the absorption fractures may occur from relatively slight violence and there is a tendency for them to be incomplete.

Treatment.—No known treatment has any effect on the progress of the condition. If fractures occur they should be properly treated and union may be expected to occur although it may be somewhat delayed. In three instances in which the patient suffered severe pain in one tibia the writer has removed a large area of the cortex over a distance of about 10 inches. This seemed to relieve the tension in the bone and relieved the pain at least over a period of a few years but did not have any effect on the general disease. A diet containing excess calcium and excess vitamins A, B, C and D is given to promote hardening of the bone. In about 10 per cent of these patients osteogenic sarcoma develops.

OSTEOGENESIS IMPERFECTA

(*Brittle Bones and Blue Sclera Hypoplasia of the Mesenchyme Osteopetrosis*)

In a case of osteogenesis imperfecta the bones are abnormally brittle and the affected person suffers fractures from relatively slight violence. There are three types of this disease. 1. Congenital osteogenesis imperfecta in which multiple fractures occur in utero and in which large numbers of fractures may be present during the first few months of life. Infants with this type rarely

survive the first year. 2 Fractures are not present at birth and usually do not occur until the child begins to be active on his feet. Then the bones may be broken as a result of falls or slight accidents. 3 This type of case is similar to the second except that the condition is inherited from one or both parents and is transmitted as a dominant hereditary character to some of the offspring. The etiology is unknown except that there is an anomaly in the development of the skeletal system.

Pathology—Pathologically the bones are characterized by being unusually slender and may show relatively coarse striations in the roentgenogram. There is no disturbance of calcification and the calcium metabolism is normal. On microscopic examination the bones are found to be quite coarse in that the Haversian canals are unusually large and may be irregular in arrangement. The epiphyses tend to be normal. The bones are not soft and do not bend but are broken by external violence.

Symptoms—In the congenital type of this disease with fractures present at birth or produced shortly after birth when the infant is lifted or moved the diagnosis is made on the basis of the presence of multiple fractures. In the second and third types the condition may not be suspected until a roentgenogram is taken and shows the abnormally slender bones. However the condition is frequently though not always accompanied by blueness of the sclera. In some patients the sclera is a clear china blue. In others there is little deviation from normal and in my experience the degree of abnormality in the sclera is not an indication of the degree of fragility of the bones. There is considerable variation in this fragility and some patients are able to lead a fairly active life while in others the bones are so fragile that the patients are practically bedridden even when braces are used and fractures are apt to occur when a relatively slight strain is put on their extremities.

The fractures are practically limited to the long bones especially the tibia and femur and a patient with a severe case may suffer thirty or forty fractures by the time adolescence is reached. The fractures tend to heal as do those of normal bone and the bone tends to be somewhat stronger at the

site of a healed fracture, but because of the repeated occurrence of fractures many of these patients are neglected and several deformities develop which could have been prevented by the adequate treatment of each fracture when it occurred.

Treatment—If the patient can be maintained through childhood there is a definite tendency in a great majority of cases for the fractures to become less frequent as adolescence is reached. This is partly due to the fact that the patient has learned to avoid injury and partly due to the fact that the bones become somewhat stronger but they never reach a point where they can be compared in strength with those of a normal person.

Since the disease appears to be due to a deficiency in the laying down of the organic matrix of the skeleton and is not dependent on any abnormality in calcification no treatment has yet been found which influences the general condition. It is important however in these cases that the fractures be adequately treated when they occur otherwise deformities will develop. In cases in which deformities have developed these can be corrected by multiple osteotomies or osteoclasis and union may be expected after such operations. Affected persons should be warned that if they have children they may be expected to inherit the condition.

ACHONDROPLASIA

This is a type of dwarfism which is due to the abnormal development of the epiphyses of the long bones or to early ossification of these epiphyses. The condition is congenital though not a hereditary bone dystrophy.

Diagnosis—The diagnosis may not be made until the second or third year of life when it may be noted that while the child's body grows normally the extremities appear unusually short though normal in thickness. In such a case rickets may be suspected but a roentgen ray examination will show that there is no lack of calcification of the epiphyses in fact the epiphyses tend to be more calcified than normal. As the child becomes older the discrepancy in the length of the extremities as compared with that of the trunk increases so that the patient has short thick arms and legs and a long relatively straight torso. The head is large and

the forehead high and prominent the bridge of the nose may be depressed. The patients are alert and normal mentally and tend to lead an active life.

Treatment—There is no treatment which is known to influence the course of the condition.

DYSCHONDROPLASIA

(Multiple Cartilaginous Exostoses)

This is a condition in which there is an abnormality in the growth at the diaphyseal end of the long bones and it is theoretically due to a failure of the periosteal sheath of the shaft to enclose the region completely and prevent the excess growth of cartilage. As a result tumors composed of a bony base, which may be either sessile or pedunculated, spring from the shafts of the long bones at or near the epiphyseal lines and project outward into the soft tissues. In the beginning these tumors are cartilaginous and as the patient grows older they become more and more calcified. In the adult they may be composed almost entirely of bone with a thin cortical layer of cartilage. The parts most commonly affected are the upper end of the tibia, the lower end of the femur, the upper end of the humerus and the lower end of the bones of the forearm. These are the regions where growth proceeds most rapidly.

A patient may have a single tumor or a dozen or more. In addition to the tumor x-ray examination frequently reveals a disorganization of the epiphyseal line adjacent to the tumor with raised areas projecting from the epiphyseal line into the cancellous portion of the shaft of the bone. In addition to the long bones the vertebrae, scapulae and pelvis may be affected. The membranes and ligaments are not affected. In a considerable percentage of patients the condition is hereditary.

OSTEOCHONDRITIS DISSECANS

Osteochondritis dissecans is a term given by Koenig to a type of loose body which develops in joints which are in other respects normal. The loose body is composed of a portion of the articular cartilage with a layer of the underlying cancellous bone. Koenig believed that the condition was due to a dissecting inflammation but repeated observations on numerous patients have connected the condition with trauma; it is now believed that as a result of a direct injury to the articular surface some of the bone loses its blood supply and becomes avascular and that this with the overlying cartilage becomes separated and may eventually become free in the joint.

When the loose body is free in the joint it manifests its presence by interfering with motion and the joint may lock from time to time the locking usually being only momentary in character but accompanied by pain. In other instances the patient has some vague pain and disability in the knee and the loose body or joint mouse is discovered roentgenographically before it has become completely detached.

Treatment—The loose body should be removed even though it is discovered before it becomes completely detached because its presence in the joint not only tends to interfere with motion but tends to cause chronic irritation in the joint and to produce chronic arthritis. If it is not removed the cartilage may continue to grow the body may become larger and may become fractured giving rise to multiple joint mice. If the loose body is in the anterior portion of the knee it should be removed by a lateral patellar incision and unless the base from which it has become detached is thoroughly healed and covered by fibrous tissue the base should also be excised. Loose bodies in the posterior capsule of the knee may be removed by a posterior lateral incision. Although they are usually found in the knee joint loose bodies are occasionally seen in the hip, elbow, shoulder or ankle and when discovered should be removed by arthroscopy.

OSTEOCHONDROSIS OF THE GROWTH CENTERS

In the various ossification centers in the child a disease may occur which commonly involves only one growth center but which may appear in several or almost all the centers in one individual. This disturbance was originally referred to as an epiphysitis since it was early described only in the true epiphyses. In recent years it has come to be recognized that any center of bone growth such as the cuboidal bones of the wrist, tarsals and vertebral bodies as well as the true epiphyses may show the same pathologic change. Since the etiology is as yet unknown and the material for pathologic study is meager, a correct and generally accepted terminology has not developed. It would seem reasonable in discussing this disease to consider whether the process involves a primary center of ossification such as the spine (before puberty) and cuboidal bones of the wrist or a secondary center viz. tibial tuberosity, capital epiphysis of the femur, patella or calcis metatarsals spine (at puberty) etc.

Some short bones and some flat bones are ossified entirely from the primary center of ossification. Nearly all the secondary centers appear after birth. Many of the secondary centers appear near the time of puberty for example in the spine, tibial tubercle, pelvic girdle, ribs, clavicle and rarely the patella.

The types of osteochondrosis under discussion are classified as occurring in either the primary or secondary groups depending on whether the primary center of ossification or the secondary center is first involved. The time of appearance and ossification of these centers is represented in figure 250. Osteochondrosis develops in ossification centers during the period of growth from one or both centers. This classification places all the cuboidal bones of the wrist and feet except the calcaneus in the primary group. The growth centers in the spine develop rather late and have two periods of active growth: the first involves the primary center during the first decade, the second the secondary centers during the second decade. A primary type may continue until the appearance of the secondary centers or the two types may appear simultaneously in the same patient.

Etiology—The etiology of this disease has not as yet been clinically or experimentally proved. It would seem however that trauma either in a direct or indirect form plays a major part in many instances regardless of location. A traumatic factor is often present in cases involving the elbow, tibial tubercle, head of the femur and second metatarsal.

Indirect violence due to increased stress and strain resulting from muscle or tendon traction is another important element. The disease is most common at the points of increased stress for example the head of the femur, the heel and the scaphoid. The vertebrae are usually involved in the low dorsal and upper lumbar region where the vertebral bodies are subjected to increased indirect trauma.

Hanson considers heredity as a possible etiological factor in vertebral disease. Leriche and Poherard offer an explanation on the basis of vasomotor changes. Since the condition has occurred in several members of the same family as well as all the growth centers in several known cases there may be some underlying endocrine or metabolic factor.

Pathology—It would appear that the pathology of this disease may be divided into two phases viz. that of degeneration and that of regeneration. In osteochondrosis of the hip it would seem that there is at first an early necrosis in the metaphysis of the neck of the femur and that necrosis later follows in the head usually at a point directly overlying the first area of necrosis in the metaphysis; it extends correspondingly in the head. It is suggestive that the degeneration in the head is the result of necrosis in the neck and so far as can be determined there is at all centers where this disease may occur a phenomenon of aseptic necrosis.

When the period of degeneration is complete the phase of regeneration begins. Regeneration is usually apparent in the metaphysis before it shows in the head. The cycle of degeneration and regeneration usually requires a period of between two and three years.

There is in the early stage subchondral necrosis of bone and marrow and an irregularity of the epiphyseal line. A lack of ossification in the early stages is noted and may

sion of the knee causes pain in the region of the ligamentum patellae. Roentgenograms show irregularity in shape as well as fragmentation of the tibial epiphysis. This common condition is self-limited, regardless of treatment. Mild cases may be relieved by cross strappings of adhesive tape, or in the more severe cases a plaster of paris splint may be necessary for a few weeks.

Kochler's Tarsal Scaphoiditis—Osteochondrosis occasionally manifests itself in the tarsal scaphoid. Its appearance in this location was originally described in 1908 by Kochler, who at the same time discussed its appearance in the patella. In the scaphoid it is frequently referred to as Kochler's disease, which is a primary type. The usual symp-

secondary type of the disease. It usually occurs in active, well developed boys between the ages of three and twelve, although girls are not entirely exempt. The first symptom is a limp, and this may be accompanied by local pain and tenderness. A certain number of patients give a history of trauma.

When the patient with osteochondrosis of the hip is first seen, the diagnosis can usually be made. Upon palpation of the hip, the head of the femur appears to be larger than normal, and the capsule does not feel thickened, as is true in tuberculosis. Some wasting of the gluteal muscles on the affected side can be seen. Some general muscle spasm, as well as pain and tenderness, may be elicited. The Trendelenburg sign is present.

Fig 251.—Roentgenogram showing osteochondrosis of the right hip

tom is aching in the region of the mid bony arch. The diagnosis is generally made by means of roentgenograms, which usually show an irregularity of contour and fragmentation of the scaphoid. The symptoms are as a rule relieved by adhesive strappings of the long arch, elevation of the inner heel of the shoe or a long arch support to be worn for a few months.

Perthes' Disease—The head of the femur is perhaps most frequently the seat of osteochondrosis. It was described by Legg and Perthes independently in 1910, and has been referred to by a number of terms, viz., Legg's disease, Legg-Perthes' disease, Perthes' disease, Legg-Calvé-Perthes' disease, osteochondritis coxae juvenilis, osteochondritis deformans, coxa plana, pseudocoxalgia or osteochondral trophopathy of the hip. It is a

Roentgenograms taken at this stage are characteristic. There is usually some broadening of the neck, with spotted areas of rarefaction below the epiphyseal line. The contour of the head may be slightly flattened, with multiple areas of rarefaction in the head.

The changes which occur in the head of the femur following reduction of a congenitally dislocated hip would appear to be those of an aseptic necrosis but arising primarily in the head of the femur rather than originating in the neck, as is suggested in primary osteochondritis of the hip.

Motion about the hip is normal unless the epiphysis has migrated to the greater trochanter, in such a case abduction and rotation are limited. Very little shortening of the leg occurs. The disease is to be differenti-

from tuberculosis coxa vara and congenital and acquired irregularities of the head of the femur as well as epiphyseal separation fractures.

The treatment whenever possible requires the child to be put to bed with Buck's extension on the affected leg, this is continued until the phase of regeneration as indicated by the roentgenogram is well advanced. When the child gets out of bed a well fitting walking brace with perineal crutch should be applied together with an elevated shoe on the opposite side. Weight bearing free of the brace should not be allowed until regeneration is practically complete.

Fig. 252.—Histological micrograph of specimen removed from the right hip (Fig. 251) showing local absorption of the matrix well vascularized but without ossification.

Apophytitis—When the disease is present in the os calcis it is referred to as apophytitis. It is the only example of the secondary type of the disease in the epiphyseal bones. It occurs most frequently in active boys between the ages of eight and fourteen years. The patient complains of pain about the heel in walking. Examination reveals pain and tenderness over the back of the heel. Full dorsiflexion is limited and any strain on the tendo achillis causes pain. Roentgenograms often show the growth center to be enlarged and irregular in outline. Areas of condensation and rarefaction occur. Relief

may be obtained by lifting the heel from $\frac{1}{4}$ to $\frac{1}{2}$ inch. A soft felt or rubber pad may be placed under the heel.

Freiberg's Infraction—Osteochondrosis of the head of the second metatarsal bone is often referred to as Freiberg's infraction. Koehler's metatarsophalangeal osteochondritis and a second Koehler's disease. This occurs most often in girls between the ages of ten and fifteen years. Local pain in walking referred to the part affected is the chief symptom. Localized tenderness, periarticular thickening and swelling are present. Dorsal flexion of the foot may be limited. Involvement of the second metatarsal bone is more common than of the four remaining bones because it is longer than the rest and bears the brunt of the body forces. Roentgenograms establish the diagnosis. The head of the second metatarsal bone is flattened and irregular. The cortical portion of the diaphysis usually shows thickening. Relief is ordinarily afforded by a leather transverse bar $\frac{3}{4}$ inch thick placed on a low heeled shoe just back of the position of the head of the affected metatarsal bone.

Vertebral osteochondrosis has usually been referred to as Scheuermann's disease, juvenile kyphosis, adolescent kyphoscoliosis, kyphosis, osteochondroproliferus, vertebral osteochondritis, vertebral epiphysitis, kyphosis dorsalis adolescentium, kyphosis dorsalis juvenilis. Attention to vertebral involvement was first aroused by Koehler in 1915. At present this is recognized as a fairly common condition more prevalent in girls than in boys.

Involvement of the primary centers may appear within the early years of life and produce a greater degree of deformity than the type occurring in the secondary centers. The secondary type is more common. In any patient with a well defined round back at adolescence this condition must be considered.

In osteochondrosis of the secondary centers of the spine the most frequent age of onset has been found to be between ten and eleven years. The incidence peak is highest earlier in girls being reached at ten years; in boys it is at eleven to fourteen years. The condition appears most frequently in the tall thin child with an asthenic constitution.

The symptoms and roentgenograms vary according to the degree of advancement of the primary or secondary types. Deformity is often the only complaint in either type. By the time the symptoms or deformity become severe enough to cause the patient to seek medical aid the roentgenograms are characteristic. There is early mottling and an irregularity of contour of the vertebral bodies most affected which are usually in the low dorsal region. The bodies may become wedge shaped resulting in angulation of the spine at this point. In the final stages sclerosis takes place and the mottled appearance decreases. The early spinal deformities may be mistaken for Pott's disease or rickets. Some of these patients complain of local discomfort at the site of angulation. The secondary centers are represented by small triangular bodies at the anterior superior and the anterior inferior margins of the vertebral bodies. The appearance of the disease in the secondary centers cannot take place until shortly before puberty when these centers appear. The roentgenogram usually establishes the diagnosis.

The treatment should be directed toward (1) prevention of deformity (2) correction of deformity if it has already occurred (3) the relief of pain and (4) the improvement of the general bodily posture.

During the early period of the disease when pain is complained of absolute physiologic rest is indicated. The child should be placed on a Bradford frame with an angulation of from 20 to 35 degrees. The apex of the curve of the spine should rest at the maximum angulation of the frame. When all muscle spasm has subsided the patient may gradually be allowed up. Sleeping on the hyperextended frame should be continued until all possible correction of the deformity has been attained. Corrective exercises should be directed toward hyperextension of the spine in such a manner as to restore the normal physiologic curves. In a few cases in which the deformity has not been corrected the patient may require a back brace to prevent an increase of the deformity or to relieve pain.

Traumatic malacia of the carpal semilunar bone of Kienbock as well as the same type of process in the spine known as *Kummell's disease* occurs in adults usually as a result

of trauma. The pathologic process probably differs from that in the juvenile form.

CONGENITAL DEFORMITIES— PART I

Madelung's Deformity—This uncommon subluxation of the wrist wherein the radius is curved forward and the ulna tends to displace dorsally is of undetermined origin though probably some disturbance of epiphyseal growth in the radius is the underlying factor. Trauma, accidental or occupational as in laundresses or clarkwomen is sometimes noted. Roentgenograms confirm the diagnosis.

Treatment—In mild cases a leather wrist support suffices. In moderately severe forms a cock up splint to the wrist leaving the fingers and thumb free is necessary. In severe cases operative shortening of the ulna and the restoration of the normal joint alignment may be required.

Congenital Clubfoot—Talipes equinovarus is often associated with other abnormalities especially spina bifida occulta. Contractures secondary to an asymmetrical development of the innervation to the muscles of the leg and muscular imbalance are a more potent cause for this condition than mechanical malposition in utero. The bones become molded and fibrous tissues also become contracted. The deformity consists of plantar flexion of the foot on the leg—

equinus inversion of the foot—varus and usually adduction of the forefoot. Torsion of the tibia and knock knee develop gradually in untreated cases.

Diagnosis is self evident in the newborn but in older patients similar deformities acquired as the result of paralysis, trauma and other causes must be excluded.

Treatment should be instituted as early as possible, preferably on the third day of life, because the muscles and ligaments must be stretched and the tarsus molded while they are still very pliable. The deformity must not only be corrected but completely overcorrected. The overcorrection must be maintained in order to allow adaptive changes in the bones and ligaments to occur and to permit the muscles to build up sufficiently so as to maintain the overcorrected position. Usually until active use in the normal position is possible a relapse must be most carefully prevented as the tendency of a clubfoot to revert is strong and persistent. In infancy gentle manipulation of the foot followed by the application of a light carefully padded plaster cast to retain the correction obtained is the method of choice. Removal of the cast in three days allows manipulation of the foot again in order to obtain further correction; this gain is held by another cast. Repetitions of manipulations and the applying of casts allow the foot to be first corrected and then overcorrected without seriously traumatizing any of the tissues or endangering the circulation.

The vessels in the foot are stretched just as much by the manipulations as are the muscles and ligaments and therefore manipulations must not be too violent. The toes must be carefully watched while in the cast for signs of swelling or an embarrassed circulation. Usually in from two to six weeks full overcorrection of the foot into a position of abduction, eversion and marked dorsiflexion can be accomplished. Then this position is held for a few weeks and finally a light clubfoot brace is applied to hold the foot in full correction. A relapse must be prevented by bracing until the patient is actively walking. Then shoes with a corrective "clubbush" shall replace the former apparatus. It is often necessary to have the patient wear a brace at night in order to guard against relapse.

An improvement in the conventional manipulation and plaster cast method was introduced by Denis Browne of London who straps the foot to separate skates or heel shoes and attaches the skates in gradually increasing degrees of external rotation to a metal cross piece 8 to 12 inches long. Active movement of the limbs when so fixed produces a sort of self manipulation and corrects both the equinus and the varus elements of the deformity without the stiffness complicating casts or other fixative measures.

The correction of the deformity becomes increasingly difficult as the child grows older and after six months of age forcible wrenching or tenotomies are often needed to supplement manual stretching. After five years of age it is sometimes necessary to resort to osteotomies to remove bony blocks that prevent correction of the deformity. The more radical measures result in some permanent damage in the foot as a mobile mechanism and are a high price to pay for delay in treatment. However even the extreme deformity seen in adults can be corrected by operative means though much of the mobility of the foot must be sacrificed in the correction.

Coxa vara exists when the angle of the femoral neck with the shaft is materially reduced below the normal 125 to 130 degrees. It is rarely congenital but usually acquired as the result of trauma, epiphyseal slipping, Legg's disease, fracture with malunion and diseases which cause softening of the bone such as rickets, osteomalacia, osteitis fibrosa, Paget's disease, etc. There is usually considerable torsion of the neck as well as the downward bending, often the pelvis tips forward and the lumbar lordosis is increased.

The *symptoms*—a limp, lameness and an inability to abduct the thighs. The *signs* include shortening of the leg if unilateral, a marked diminution of Bryant's line with a high and prominent trochanter and loss of abduction, rotation and extension of the hip. In severe cases the mechanical disability in the hip is so great that the symptoms and signs of joint irritation and muscle spasm are found. A *differential diagnosis* between coxa vara and inflammatory lesions such as tuberculosis is made roentgenographically. *Treatment* depends on the age of the patient and the underlying cause. In young children

with soft bones, manipulation and fixation in forced abduction followed by protection against weight bearing is advised. In early epiphyseal slipping at adolescence, manipulation and fixation is again useful. In adults, or in cases in which the deformity has been of long duration, corrective osteotomy just below the trochanter allows correction. The underlying cause must be discovered and treated, or recurrence is certain.

Coxa valga is just the opposite of *coxa vara*. In this deformity the angle of the femoral neck with the shaft is 150 degrees or more. As weight bearing is the force which causes *coxa vara*, so a lack of normal weight bearing is the most important factor in *coxa*

valga; the luxated femoral head is opposite the acetabulum but not firmly engaged in it. With activity the head moves freely, and as weight bearing begins, dislocation upward and backward starts. The head carries with it the stretching capsule and ligamentum teres. The dislocation increases until the head comes to be in contact with the ala of the ilium, where it may eventually hollow out a false acetabulum. The true acetabulum fails to develop, and its shallow cup may be filled with fat and fibrous tissue. The head of the femur becomes irregularly flattened and the neck shortened and twisted as its abnormal contacts mold it. The elongated capsule often becomes contracted to an hour-

Fig. 255—Untreated bilateral congenital dislocations in adult showing late bone changes in the femurs, acetabulums, iliums, and pelvis.

valga. It is found in paralytic conditions especially, though it is curiously enough seen in rickets also. It is not in itself a serious deformity, like *coxa vara*, but will usually disappear spontaneously if normal functional use of the leg can be restored.

Congenital dislocation of the hip is a common and serious malformation. It is more common in certain districts of Europe than in this country and is very rare in the colored race. Eighty-five per cent of cases occur in females. It may be single or bilateral. A large majority of the single cases occur in the left hip. The cause of the deformity is as yet undetermined, but heredity is certainly a factor. Unlike most congenital deformities, it is not recognizable at birth. In early in-

glass shape, and the long muscles of the thigh shorten. The upward thrust of the limb posteriorly tips the pelvis forward markedly, and extreme lumbar *lordosis* results. These changes take place rapidly after the child starts walking, so that the condition usually is noticeable at an age of from fourteen to eighteen months.

The *symptoms* are a limp if unilateral; a waddle if bilateral. There is no pain during childhood. The *signs* include shortening of the leg with a riding of the trochanter above Nélaton's line; a widening of the perineum, Trendelenburg's sign—a dipping of the pelvis to the opposite side when weight is borne on the dislocated hip; and lumbar *lordosis*. The *diagnosis* is indicated by the aforemen-

tioned signs coupled with free mobility and no protective muscle spasm despite marked limp. Roentgenograms confirm the diagnosis. *Treatment* consists of manipulation under anesthetic as introduced by Lorenz and modified by Denuee and should be started as soon as a diagnosis has been made. Delay only increases the displacement and distorts the contours of both the head and the socket. A few weeks of preliminary traction may aid in stretching the contracted long muscles and make manipulation easier. Violence must be avoided or damage to the growing femoral epiphysis results. Reduction can usually be obtained by following Denuee's technique but the great difficulty is to prevent redislocation. After reduction a plaster fixation is required for from six to eighteen months to allow shortening of the stretched capsule and deepening of the acetabulum from pressure by the head. Redislocation is usually caused either by an inadequate rim of the acetabulum or by interposition of an hour glass capsule between the socket and the head as reduction is attempted. Every passing year beyond two years of age doubles the difficulty of reduction and after eight years of age manipulations are practically useless.

If manipulation fails or redislocation occurs upon reduction is indicated. When even operation fails to restore and maintain normal relations a false acetabulum may be made or deepened and a bony flap turned down from the wing of the ilium to give a shelf against which the body weight can be stabilized.

In adult cases in which both the dislocated hip and the extreme limb arthrosis result in severe pain and disability, arthrodesis of the hip may be done in unilateral cases.

Congenital wryneck, or torticollis, is usually due to contracture of the sternocleidomastoid muscle though occasionally bony at normality causes a severe and intractable deformity. The muscle may become contracted in utero or may undergo fibrosis and shortening secondary to stretching and tearing during delivery. In many cases a hematoma in the muscle can be palpated in the first week. The contracted muscle tilts the head to the affected side and turns the chin to the opposite side. Asymmetry of the head, face and spine and even of the shoulder and

thorax results in uncorrected cases. There are no symptoms or signs other than the deformity.

The diagnosis is not difficult to make but it is important to differentiate the congenital type from the type acquired secondary to inflammatory lesions (tuberculosis) of the cervical spine, cervical lymphadenitis, arthritis, infections or post traumatic, overstrain etc. In the latter only the exciting cause should be treated actively while in the congenital cases the muscle itself must be attacked.

Treatment—In early infancy the deformity may be overcome by gentle stretching massage and the use of sand bags to hold the head straight. In older cases manipulation and exercises plus bracing may be sufficient for mild contractures but as a rule release of the contracture by operation is necessary. The muscle may be freed either from its origin or from its insertion the head can then be overcorrected and fixed in plaster until healing occurs in the stretched position.

ROBERT W. JOHNSON, JR.

CONGENITAL DEFORMITIES— PART II

Congenital clubhand is usually accompanied by a defective development of the bones of the forearm. The deformities of the hand may be forward, backward or lateral or a combination of these. The simple clubhand is somewhat similar to clubfoot and the condition is assumed to be caused by malposition in utero. There may be other congenital deformities present. The second type of clubhand is associated with congenital contractures and other deformities (Fig. 254). The type most often seen is associated with an absence or a defective development of the radius and the hand assumes a right angled relation with the ulna. In the simple clubhand early manipulation and retention of the hand in the overcorrected position by splints is indicated. Massage is given to overcome contraction and to restore good circulation. In the second type when the condition is associated with deformity of the bones of the forearm the outlook for correction of the hand is extremely poor and simple procedures to maintain as much use of the hand

which are caused by osteocartilaginous bodies. Injury of the ligaments especially of the crucial ligaments is more common than is generally supposed in mechanical derangements of the knee and examination as to the integrity of these ligaments should be made in every case. Many of the unsatisfactory results which occasionally follow removal of fractured menisci are the result of injury of the crucial ligaments usually the anterior, which is not recognized before operation and failure to secure complete recovery is wrongly laid to the surgical treatment. (See section on Ligaments.)

THE SEMILUNAR CARTILAGES

The internal semilunar cartilage is somewhat C shaped and rests on the inner tuberosity of the tibia the external semilunar cartilage is more nearly circular and rests on the outer tuberosity of the tibia. Both serve to deepen somewhat the cavities for the reception of the condyles of the femur. They are fibrocartilaginous in character and do not cast a shadow in roentgenograms except in rare instances when calcium is deposited in their substance. Owing to their fibrocartilaginous nature they tear in their long axis rather than fracture transversely. This peculiarity accounts for the varied types of fractures which are encountered. The internal semilunar cartilage has a firm attachment to the capsule of the joint whereas the external cartilage is more loosely attached a point to be remembered for it has an important bearing on the pathologic changes which are present in derangements of the respective cartilages.

Injury to the internal meniscus is eight times more common than injury to the external meniscus although some authorities place the ratio as low as 4 to 1 or 5 to 1. The chief reason for this fact is the firm attachment of the internal cartilage to the internal capsule really the internal lateral ligament. The external cartilage is loosely attached to the external capsule and thus has a certain amount of mobility which allows it to slip from between the ends of the bones when it is caught. This is not true of the internal cartilage for it is so firmly attached to the lateral capsule that it will rip or tear in its own substance rather than break loose from its moorings.

TRACTURES OF THE MENISCI AND THE MECHANISM OF PRODUCTION

The menisci lie well toward the peripheral margin of the joint away from the bearing surfaces and normally offer no obstruction to motion. Inasmuch as the internal semilunar cartilage is most often fractured discession will be confined chiefly to it. This cartilage is most deeply placed within the joint when the knee is partially flexed and the foot everted in which position the head of the tibia is rotated outward slightly on the femur. If this position of eversion of the foot with consequent outward rotation of the tibial head is maintained as the act of extension is carried out the inner condyle of the femur may roll down on the internal meniscus and grip it. Unless the act of extension is stopped in time one of two things must happen either the internal semilunar cartilage must be torn from its moorings and dragged toward the center of the joint or it must tear in its substance. The latter is what actually occurs. The exact location of the tear or fracture in the meniscus will depend on the point at which it is nipped. It may be in the anterior middle or posterior portion. The force causing the derangement may be so great that the blocking action which terminates in the final giving way (fracture) of the meniscus will not be sufficient to check it and continuation of the force may drive the knee into hyperextension and rupture the anterior crucial ligament. When the anterior crucial ligament is so ruptured the tibia slips forward on the femur, and an unstable knee results. This hypermobility is rarely marked but it can be detected by having the patient sit on a hard chair or table and allow the leg to dangle over the edge in such a manner that the knee is flexed at a right angle. If the head of the tibia can be pulled forward appreciably on the femur it is evidence of a rupture of the anterior crucial ligament. Persons differ in the amount of mobility which is normally present therefore the affected knee should be compared with the sound one. Operations for repair of this ligament have been devised but are seldom indicated.

Symptoms and Diagnosis.—Injury of one of the semilunar cartilages occurs generally among males who are in the active period of life and engaged actively in work

or games. On the other hand it may be independent of any unusual activity and it has been known to occur while the patient is recumbent in bed when locking of the joint results merely from turning over. The event in any case is accompanied by pain by inability to extend the knee and by swelling. Pain is usually located on the side of the involved cartilage but not infrequently the pain is described as generalized. The knee is held in partial flexion (locking) but may be released and straightened by the active efforts of the patient himself or someone may pull on the leg for him and it will

gradually grind the obstructing portion of the cartilage to such fine shreds that no obstruction finally is offered. On close questioning of the patient it is almost uniformly discovered that at the initial attack particularly when the internal meniscus is concerned the knee was partially flexed the foot was abducted and rotated outward thus throwing the strain on the internal lateral ligament and as the act of extension continued the catching occurred.

In the majority of instances of derangement of the knee joint that are the result of injury of the semilunar cartilage a tear or

Fig. 5—Types of fracture of internal semilunar cartilage

straighten often with an audible snap. Usually recurrent lockings ensue and their irregularity makes steady employment difficult. Although the attacks may increase in frequency, the tendency is for the pain swelling and period of incidental disability to decrease. An actual fracture or tear in the meniscus may not be produced at the initial attack but as the attacks recur with catching and squeezing of the cartilage between the ends of the bones, a fracture is usually produced. Sometimes when the condition affects vigorous men who pay little attention to pain the repeated lockings

fracture will be discovered in the meniscus which is involved. However a cartilage may be hypermobile as the result of a lax capsule so that it occasionally will be caught and pinched between the ends of the bones but it will not be actually fractured. The most common type of tear or fracture is that which has been called a bucket handle fracture or loop fracture. This is a longitudinal tear in the middle portion of the cartilage leaving the anterior and posterior ends intact so that the mesial portion of the cartilage is crowded over into the intercondylar notch in the form of a loop (Fig. 255). The

mesial portion of the loop of the cartilage in this position obstructs extension and full flexion usually cannot be attained. This type of fracture occurs in both the external and internal semilunar cartilages. There are other common types of tear or fracture of the cartilage (Fig. 255). The more common types are (1) the bucket handle fracture, (2) the longitudinal pedunculated flap with its base either forward or posterior in the anterior third and (3) the tears in the middle and posterior thirds which likewise have their bases either forward or posterior (Fig. 255). The latter may produce bizarre symptoms of transient catching. Effusion varies in individual cases.

A bucket handle tear which is caused by the primary injury may have such a large thick hop lying in the intercondylar notch that the knee cannot be straightened even by manipulation under anesthesia. The loop may persist thus for months all swelling and pain may leave and the only symptoms may be a feeling of insecurity and inability to extend the knee completely. In these rather rare instances removal of the cartilage is indicated even though there has been but the single attack. The patient may note the lack of extension only when told to stand erect with the feet together and to straighten both knees.

Differential Diagnosis.—Arthritis either tuberculous or infectious may produce swelling and edema of the synovial membrane. Little falls of synovia may be nipped between the bones but the pain which results from this pinching is not severe. One should be cautious about making a diagnosis of mechanical derangement of the knee joint when a thickened capsule is present and particularly if other joints give evidence of arthritis.

Recurrent dislocations of the patella which usually affect women are also sudden in onset and painful but the patient as a rule observes that the patella is displaced outward. Sometimes a definite diagnosis is difficult and under such circumstances surgical intervention should be postponed meanwhile the patient should be asked to note carefully the subjective and objective symptoms which occur during the next attack.

Conservative Treatment.—When one

first examines a patient with a mechanical derangement of the knee joint which is the result of an injury to the internal semilunar cartilage the knee should be manipulated and straightened. This may be done without anesthesia in many cases. The patient should lie recumbent preferably on a low, flat firm table and the knees should hang over the end. The surgeon stands between the patient's legs and flexes the affected knee as fully as possible holding the patient's ankle firmly in one hand while the thumb of the other hand presses over the anterior end of the cartilage which is involved. With the cooperation of the patient and at the count of three the knee should be forcibly extended and at the same time the tibia should be rotated inward. This movement tends to release the torn or fractured portion of the cartilage. If the knee goes into complete extension and the patient says that the knee feels right all is well but if this reassurance on the part of the patient is lacking the probabilities are that reduction has not been accomplished and that the maneuver should be repeated. If neither surgeon nor patient is satisfied the chances are that a bucket handle fracture is present and that the loop is held firmly in the intercondylar notch. If reduction is satisfactory a posterior splint should be applied; this should be worn for ten days or until all soreness and swelling have subsided. Diathermy or radiant heat may hasten absorption of the effusion. If the cartilage was merely pinched and not fractured subsequent locking may not occur but if there was a fracture attacks of locking almost certainly will follow, and removal of the offending meniscus will be necessary. If reduction was not accomplished satisfactorily the patient should be put to bed and the leg should be held as nearly straight as possible in a comfortable position. Heat at forced relaxation and as the swelling subsides the knee may straighten of its own accord without the act of reduction being definitely noted. If it stays locked exploration is advisable.

Surgical Treatment.—More than a single locking should have occurred before one resorts to surgical treatment save in the exceptional cases which have been mentioned.

The utmost care must be used in establishing a definite diagnosis as to which men-

is involved for there is no single incision that gives free opportunity for exploration of both. Even an extensive longitudinal split patellar incision does not do it and this is now used by very few surgeons. Generally speaking if the internal meniscus is involved the pain extends to the inner side of the knee and if the external meniscus is the offender the opposite is true. Pain is caused by tension on the capsule and ligaments not by the pressure on the meniscus or joint surface. It is possible though not common for a fracture of an external cartilage to distort the joint that pain is referred to the inner side of the knee. The roentgenogram is of no aid because the meniscus casts no shadow.

The preparation of the knee for operation is important. Infected abrasions and pustules in the skin are dangerous and an knee joint should be opened when they are present. The leg should be cleansed with soap and water at the time of shaving and a sterile bandage should be applied but the actual preparation may be done on the operating table. No more care is necessary here than is required in the preparation for any other operation, there are no grades in preparation but the exact method that is employed depends on the choice of the individual surgeons. After adequate preparation of the skin the leg is properly draped a tourniquet is applied the foot of the operating table is dropped and the patient's leg is allowed to hang over the edge of the table at a right angle. The skin incision for removal of the internal meniscus need not be long about 5 cm. in length is sufficient it begins 1.5 to 2 cm. to the inner side of the patella and extends downward from the level of the middle of the patella to a little below the level of the head of the tibia.

If a fracture is present in the cartilage as much of the torn portions of the cartilage as possible should be removed three fourths is usually sufficient and care must be taken not to injure the internal lateral ligament. If no fracture is discovered the patellar tendon should be pulled forward with the aid of a smooth retractor so that one may look across into the external compartment of the joint to see if the external cartilage is injured. This method of exploration of the external compartment is not really satisfactory

however and if no abnormality has been disclosed and if the symptoms warrant it, a separate external incision should be made. If no abnormality is seen and if the history of recurrent locking with pain which extends to the inner side of the knee is definite the internal meniscus may be removed if the surgeon feels that the disability is great enough to warrant it. Occasionally when the anterior portion of the cartilage is loosened and the meniscus pulled forward a fracture will be found in the posterior third which could not have been determined in any other way. If the posterior portion of the cartilage must be removed a posterolateral incision which is made just anterior to the ham strings is particularly useful especially in those cases in which a lesion of the posterior third of the cartilage is suspected and in which its removal is deemed necessary. The capsule of the joint should be closed in layers and the knee should be put up in extension either on a posterior splint or in a plaster of paris cast which is split. If the external cartilage is to be removed a similar incision on the outer side should be employed. Unless there is considerable effusion the cast may be removed after five days and gentle movement permitted. If all is well the patient may be permitted to bear weight and walk eight to ten days after the operation.

OSTEOCARTILAGINOUS BODIES

Osteocartilaginous bodies cause derangements of the knee that are less severe than are those which are the result of disturbances of the semilunar cartilages. Sometimes the patient himself is able to palpate and localize the bodies and they are always visible in roentgenograms. In rare instances the derangement is the result of involvement of both a semilunar cartilage and the osteocartilaginous bodies. The bodies may be entirely free and may wander about the joint they may become smooth and rounded they may be attached by a pedicle to the synovial membrane or they may be held embedded in synovial membrane. In the latter case they are rougher and mulberry like in appearance. The chief interest surrounding these bodies concerns their etiology and they are best classified under three headings:

1. Some osteocartilaginous bodies are the

result of *osteoarthritis* and usually affect persons who are beyond middle age. The bodies originate from the marginal osteophytic growths which do not break off completely at first but remain attached for a time by a pedicle that contains blood vessels. These bodies increase in size and finally break away from their pedicles to wander as free bodies in the joint. While the body is attached by a pedicle the bony substance may increase but this ceases after the body breaks away from the pedicle; however the joint fluid affords sufficient nourishment for the outer cartilaginous layer to increase in thickness. In *osteoarthritis* the bodies are multiple; there often are as many as five or

symptoms may be indefinite and the patient may have a feeling of insecurity in the knee. The patients are usually in young adult or early middle life. Hystero-genesis should be carefully studied to detect any abnormality on the surface of the internal condyle.

3 Loose bodies which are the result of *osteocondromatosis* may be quite numerous and may cause the knee to feel like a sack of marbles (Fig. 257). *Osteochondromatosis* is in reality a benign neoplastic process which produces osteocartilaginous bodies particularly at the attachment of the synovial membrane to the bone but they may arise from any area of the synovial membrane. The bodies first appear as little fleshy nodules

Fig. 256—Loose body in *osteoarthritis dissecans* arising from the internal condyle.
Fig. 257—*Osteochondromatosis* of the knee with multiple loose bodies.

six. Patients in this group are usually elderly and unless the bodies are causing discomfort they may be left.

2 Loose bodies may be the result of *osteocondritis dissecans*. This is a rather unusual condition that deserves a more lengthy consideration than can be included here. The bodies are formed as the result of separation of a piece of osteocartilaginous substance from the articular surfaces of the knee, usually from the internal condyle of the femur just proximal to the insertion of the posterior cruciate ligament into the internal condyle (Fig. 256). The bodies are usually single and both knees are occasionally involved. The body may arise from the external condyle, the tibia or the patella. While the process of separation is going on the

that become cartilaginous at the tips, they grow in size and hang into the cavity of the joint by pedicles which break as the bodies become too heavy. Several cases have been reported in which the bodies exceeded a thousand in number.

Symptoms—Regardless of the origin of the bodies, the symptoms which they produce are the same, namely, catching or locking of the joint with pain. Swelling rarely follows and the pain is of short duration. In young persons the presence of these bodies *per se* is sufficient indication for their surgical removal but in elderly patients as has been mentioned previously they may be left undisturbed. Removal of such bodies should be done under the strictest aseptic conditions. Too often removal of these bodies

in the office has led to seriously infected joints with dreadful sequelae.

AMYOTONIA CONGENITA, CEREBRAL SPASTIC PARALYSIS, SPRENGEL'S DEFORMITY, POLIOMYELITIS

AMYOTONIA CONGENITA

(Oppenheim's Disease)

Definition.—A congenital weakness of muscle, local or general, characterized by hypotonus and flabbiness.

Etiology.—The etiology is congenital, otherwise unknown.

Fig 258—Amyotonia congenita (New England Free-body Home case)

Pathology.—The muscle fibers occur in clusters. Some are small and fetal in type, and others are increased in size.

Symptoms.—Generalized weakness and loss of tone in local groups of muscles or involvement of practically all the muscles of the body are symptoms of this disease.

There is not complete loss of power. The reflexes are absent. The disease resembles in some respects a generalized poliomyelitis. Contractures occur in the extremities.

Treatment.—Treatment includes physiotherapy, the avoidance of fatigue and the correction of contractures by stretching, tenotomies or fasciotomies as indicated.

CEREBRAL SPASTIC PARALYSIS IN CHILDREN

(Little's Disease)

This affection is not a true paralysis but rather an increase in muscular tone due to a loss of inhibitory control in the central nervous system. It is characterized by disturbances in locomotion from exaggerated muscle movements. The affection may be confined to one extremity, monoplegia, one side of the body, hemiplegia; two extremities, paraplegia, or both sides of the body, diplegia.

Etiology.—This disease is probably due chiefly to developmental defects in the central nervous system. Prolonged or precipitate labor with damage to the brain from hemorrhage and bad obstetrical technique or asphyxia are also considered from an etiological standpoint.

Pathology.—The lesion is situated in the motor area of the brain, sometimes associated with hemorrhages in the basal ganglia. As a result, there are disturbances of development, atrophy of brain tissue, sclerosis and sometimes calcification, and also degeneration of the pyramidal and lateral tracts of the cord.

Symptoms.—The symptoms depend on the extent of the lesion and the amount of disability. The muscles show increased tone on palpation. Small children react very suddenly, with dissociated movements, to sudden noises. Active muscular efforts increase the spastic movements, and walking and the use of the hands show slight impairment of function up to complete inability to do anything. In the monoplegic type there is no

equinus with a clinging gait in walking. In hemiplegia the arm is held flexed at the wrist, fingers and elbow, the forearm is pronated and the shoulder is adducted. In paraplegia, which is the most common form, there are the symptoms seen in monoplegia plus a scissors gait. The knees and hips are adducted and internally rotated. In diplegia there are the symptoms of hemiplegia on each side. Exaggerated reflexes and clonus are important symptoms. The deep reflexes are increased and the Babinski and Oppenheim reflexes are often present. At times the

Fig. 259.—Spastic paralysis: Diplegia, crossing position (C. J. Allen's Hospital case)

hypertonicity in all the muscles is so great that the reflexes are not obtained at all. The gait may be ataxic with a lack of rhythm, coordination and balance.

Athetosis is often seen associated with the spastic condition. These athetoid movements are dissociated, occur involuntarily and are always exaggerated when the patient attempts to perform some act. A generalized athetosis may exist alone. Many of these patients are labeled as mentally retarded when such is not the case. Mental retardation is often seen, however, in true spastic paralysis, and sometimes the contrary is

true, i. e., the mental development may be above normal.

Diagnosis.—The diagnosis is based on the general picture and should not be difficult even in the mild cases if a careful examination is made.

Prognosis.—The prognosis depends on the extent of the lesion in the extremities and the mental status. Extensive athetoid movements make the prognosis poorer since it is much harder for those so affected to control their movements.

Treatment.—The treatment includes (1) testing the mentality of the patient, (2) removing all sources of outside irritation, (3) using good discipline and (4) avoiding fatigue.

If the mental retardation is not too great and one can expect cooperation from the child and his parents, then one may outline a plan of treatment suitable to each individual case. It is well before considering operative measures to begin by using proper physiotherapeutic exercises in muscle re-education, balance, coordination and rhythm. Massage and electricity aggravate an irritable limb and serve no good purpose. All sorts of devices can be used to stimulate the function of the affected muscles.

The different forms of *operative treatment* are divided into two groups: (1) operations on the muscles in which myotomy or tenotomy is done and tendon transplantation, (2) and operations on the nervous system—infiltration of nerves with alcohol, section of motor nerves (Stiff's operation), division of posterior nerve roots (Forster's operation) or ramisection (Ravle).

time the biceps tendon is divided. If there is bony obstruction to complete extension an osteotomy should be performed. In many instances the patella is higher than normal. In case this is so it will be necessary to insert the patellar tendon down on the tibia, using skeletal traction by means of a pin through the patella and incorporated in the plaster and left for three weeks. Unless this is done the patient will not have power enough in the retracted quadriceps muscle to extend the knee completely. The leg should be kept extended after these operations for from six to eight weeks in plaster.

Adduction contracture may be relieved by dividing the adductor muscles completely. The legs must be kept abducted for from eight to twelve weeks in a plaster spica. If there is much abductor weakness Legg's operation should be done. This operation consists in freeing the tensor fasciae latae from its surrounding structures and transplanting the upper portion which has been freed to a place more posterior so that it acts as a pure abductor. This operation also helps to remove inward rotation and hip flexion contracture.

Scoliosis is usually due to muscle contracture of the spinal and lateral abdominal muscles and may be relieved by dividing the lumbar fascia and the short erect intermuscular septa in this region.

Flexion and Adduction of the Hand—The flexor carpi ulnaris may be transplanted into the dorsal surface of the base of the third metacarpal bone relieving the adduction and assisting dorsal flexion. In pure flexion deformity tenodesis of the extensor carpi ulnaris in the ulna and of the extensor carpi radialis brevis to the radius holding the hand in the cosmetic cock up position will improve the function of the hand tremendously. The hand must be kept overcorrected for six weeks.

Pronation contracture of the forearm necessitates a Jones operation. The pronator radii teres tendon is completely freed from its insertion and sutured as low down as possible into the two radial extensors. The wrist is kept dorsiflexed.

Adduction contracture of the shoulder may be relieved by section of the pectoralis major and subscapularis tendons.

Operations on the Nervous System—1 Infiltration of the motor nerves with strong alcohol results in temporary paralysis which lasts for from six to eight weeks. This procedure permits one to carry on physiotherapy to a better advantage since the contracted muscles do not function.

2 Section of the posterior nerve roots or Forster's operation consists in division of the third fourth and fifth lumbar and the first and second sacral dorsal roots to relieve spasm in the lower extremity and the division of the last four cervical and first thoracic roots to relieve spasm in the upper extremity. This operation is very severe on the patient and is practically never done in this country for this type of paralysis.

3 Division of motor nerves. Stoffel's operation consists in resection of at least 2 inches of a motor nerve that goes to a spastic muscle. It has been performed on the internal popliteal nerve for equinus the sciatic branches to the hamstrings the obturator and the

median nerves. The results on the first three nerves are not as successful in general as they are on the obturator and median nerves. Resection of the anterior cord and the median nerve is excellent in cases of pronation spasticity. The proximal portion of the cut nerve should be sutured to the fascia so as to prevent regrowth.

4 *Ransection of sympathetic nerves* as advocated by Royle has not been generally successful. In cases of increased spastic tone it does seem to be helpful and it also increases the surface temperature of the extremities.

5 Section of the anterolateral tracts is advocated by Putnam in cases of athetosis. Marked improvement results in some cases.

Summary—There are numerous operations advocated in the management of spastic paralysis but none of them cures the condition. The whole object is to remove deformities and disabilities in order that one may proceed with the real treatment which is physical education. Each individual case must be considered from the physiologic aspects of the neuromuscular mechanism. These patients must be taught how to relax. The exercises given must be simple and since the spastic attitude is that of protection, it is necessary to attack the extensor muscle groups.

Most of these patients are lacking in balance, rhythm, precision and coordination. To obtain the desired improvement in these conditions means treatment over a long period and requires gentleness and patience on the part of the physiotherapist.

SPRENGEL'S DEFORMITY

(Congenital Elevation of the Scapula)

This type of congenital deformity is an upward displacement of the scapula. It is usually unilateral but bilateral lesions are seen occasionally.

Etiology—It is a primary deformity and other primary deformities also may be present.

Pathology.—The scapula is smaller than its fellow. The supraspinous area is hooked sharply forward. Four types may be found: (1) the type in which there is no connection between the scapula and the spine, (2) the type in which there is a fibrous band extending from the vertebral end of the spine of the scapula to one of the cervical spines, (3) the type in which there is a cartilaginous isthmus, and (4) the type which shows a bony isthmus, wide at its base and with a definite part of the scapula extending obliquely upward and forming a fairly solid articulation with the spine.

Fig. 260.—Scapula deformity (Children's Hospital case)

Symptoms.—The scapula is high and rotated forward, making an unsightly prominence at the root of the neck. Torticollis and scoliosis may accompany the lesion. Limitation of abduction and elevation of the arm are usually present.

Diagnosis.—The diagnosis is made from a study of the symptoms and is confirmed by the roentgenogram.

Prognosis.—If the condition is not treated, it becomes increasingly unsightly. Operative intervention will improve it cosmetically and is nearly always satisfactory.

Treatment.—Mild cases are helped by special exercises. The majority, however, are severe, and operation is indicated. There are two objects to be obtained: first, removal of the deforming elements and, second, depression of the scapula.

It has been the custom in many clinics to make an incision parallel to the spine of the scapula, to remove the muscular attachments in the supraspinous area, both anteriorly and posteriorly, subperiosteally, and to divide or to remove connecting links leading to the spine. In some instances the scapula is pulled down as far as possible and attached to a rib by means of fascia or other suture material. The writer's method is as follows:

1. The deforming elements are removed as previously described except that the muscles are cleared from the periosteum since it has been found that the supraspinous fossa may grow back where a subperiosteal division is made.

2. A hole is drilled through the center of the spinous process and a double strand of dental wire is threaded through it.

3. A second incision, 1 inch long, is made 2 inches below the tip of the scapula, and all free ends of the wire are drawn down beneath the muscles of the scapula emerging from the lower wound.

4. A long plaster strip, open at the back of the waist line, is applied to the leg and a ring is attached. As soon as the patient is comfortable, skeletal traction is begun using a spring balance with from 6 to 8 pounds of weight. This is continued until the scapula is pulled down and requires about four weeks. At the end of this period, a 4 inch incision is made over the dorsal spine, exposing the superficial spinal muscles and fascia. A flap of muscle and fascia, 4 inches long with the base down is freed and entered to the inferior angle of the scapula subperiosteally. This maneuver allows for more flexibility of the scapula and at the same time holds it down.

POLIOMYELITIS (Infantile Paralysis)

Definition.—Polio-myelitis is an acute infectious disease having general constitutional and central nervous system manifestations, usually localized in the anterior horn cells of the spinal cord and often characterized by motor paralysis.

Etiology.—The infecting organism is unknown, but recent research has produced strong evidence that a filtrable virus is an

etiological agent. It occurs in sporadic and epidemic forms. There are certain areas where it is practically always prevalent, more especially in the northern part of the north temperate zone. The majority of the cases are seen during the summer months, although a few cases appear throughout the winter months.

Pathology.—The early pathology is a primary invasion of the meninges with perivascular infiltration, hyperemia and edema of the cord. As a result of this inflammatory process the delicate vessels leading to the anterior horn cells and the cells themselves are pressed on, shutting off the circulation and causing necrosis and temporary loss of function. If there is no relief from pressure of the exudate, necrosis results and the damage to the individual cells is permanent. The posterior root ganglia are probably always involved. In occasional cases there is similar involvement of the brain medulla and pons. When cells are completely destroyed they are replaced by cicatricial tissue—'focal gliosis'. Owing to the vertical overlapping distribution of the anterior horn cells, it is rare to see a total motor paralysis.

Symptoms.—There may be no history of early symptoms. A child apparently well may go to bed at night perfectly well and may be found to be paralyzed in the morning. The usual early symptoms are constitutional and include fever, malaise, headache, mental irritability, gastrointestinal disturbances, coryza, pharyngitis and tonsillitis. Quite often there is general hyperesthesia. Photophobia is sometimes noted. Associated with all these symptoms is stiffness of the neck or back, varying in degree from a very mild type to extreme rigidity. Tremor and pain in the extremities are usually present. These symptoms occur in what is known as the prodromal stage, i. e. before the paralysis appears. Lumbar puncture should be performed at this time. Early the deep reflexes may be increased, late they are diminished or lost.

For the sake of clearness, Lovett divided the disease into three stages as follows: acute, convalescent and chronic.

1. Acute Stage.—The acute stage covers that portion of the disease from the earliest symptoms to the disappearance of the tenderness. Tenderness is probably evidence

that the inflammatory condition in the cord has not subsided.

2. Convalescent Stage.—There is retrogression of the inflammatory process, and if paralysis is present, it is well established. The muscles begin to show improvement and circulatory disturbances and atrophy are more and more apparent. The arbitrary length of this stage is two years, but the writer has seen in many instances a returning muscular function over a long period of years.

3. Chronic Stage.—Spontaneous recovery has by this time slowed down considerably. Deformities have become more or less permanent and atrophic and circulatory changes are more noticeable.

Distribution of the Paralysis.—Paralysis which is rarely symmetrical is more often confined to the lower extremities, the anterior tibial muscle being the one most frequently affected—one leg or both, either partially or completely. The extensors of the knee are more often paralyzed than the flexors. Thence muscles most often spared are the peroneals, sartorius and the tensor fasciae latae. The abdominal muscles are rarely spared and the spinal muscles are rarely affected. The anterior neck muscles are practically always affected, even in very mild cases. There is a transitory neck drop in practically all cases. This is not due to paralysis of the neck muscles. Lateral paralysis is seen in about 30 per cent of all cases. There may be paralysis of the muscles of deglutition, the soft palate, the pterygoids and respiration. The upper extremity may be totally paralyzed, but the deltoid and opponens pollicis are most commonly affected.

Sensory disturbances are sometimes observed, but they are evanescent, mild and never permanent. Paralysis of the bladder may be a complication, but complete recovery within six weeks is the rule.

Tenderness often associated with muscle spasm is noted early when the paralysis is established and may be very severe and even distressing. It does not follow the distribution of the paralyzed muscles, for it is seen in an extremity that is otherwise perfectly well. The usual situation of the tenderness is in the calf, anterior thigh, buttock, anterior hip muscles, back and axillary muscles. The tenderness may be so severe that

the child cries at the least jar or movement. Flexion deformities of the legs and adduction of the arms occur as a result unless proper treatment is instituted. The period of tenderness may last for from a few weeks to a year or more.

Fig. 201—Hyperextension of the knees in poliomyelitis. (Children's Hospital case.)

Diagnosis.—The diagnosis is missed frequently because the physical examination has been hasty and incomplete. The disease is often mistaken for "acute rheumatism," "grippe," "sore throat," "typhoidness," or "osteomyelitis." Given the symptoms just described the physician should test for stiffness of the neck. We should not be satisfied with mere raising of the head, because all the posterior spinal muscles are affected. In a mild case the test must be made with the patient lying on his side and with the whole body, including the neck, flexed. In the presence of a stiff neck or back, lumbar puncture is always indicated. The spinal fluid is usually clear but may show a faint ground glass appearance. There is often increased pressure; the leukocyte count is increased—usually there are mononuclears, but there may be a high percentage of polymorphonuclear cells; and there is an increase in globulin.

Prognosis.—In all cases the mortality rate is about 20 per cent in this country. Death is due to respiratory paralysis or pulmonary complications. When recovery takes place the prognosis as to function must be guarded, especially in the tender stage. In

most instances, however, there is practically always improvement and sometimes complete recovery. There is the so-called abortive type which shows the characteristic constitutional symptoms but no paralysis. Shortening of an extremity may or may not occur.

Treatment.—In the acute stage the treatment is medical and good nursing is valuable. When there is respiratory difficulty, it may be necessary for the patient to live in a Drinker respirator. Tenderness and spasm are treated by the application of heat in some form, hot saline baths and early frequent applications of hot packs seem to give the best results. (Pohl and Kenny.)

The extremities if paralyzed must be kept on wire splints in the most comfortable position. As the tenderness subsides the splints may be gradually straightened until the extremities are in such a position that no contractures will occur. Massage should not be given during this period.

Prevention of Deformities.—The patient should not be permitted to assume positions

Fig. 202—Scoliosis in poliomyelitis. (Children's Hospital case.)

favoring contractures. Deformities, however, should not be corrected if in so doing the tenderness is increased; otherwise a mild deformity may be converted into a troublesome one. Absolute rest must be insisted on during the acute stage. Any form of treat-

ment at this time such as massage electricity and exercises is meddling and serves to prolong this stage.

Convalescent Stage—As soon as it is apparent that all tenderness has subsided measures to rehabilitate the affected muscles may be begun. To this end it is necessary that a complete examination of all muscles be made in order to determine what the physiologic problem is. For clearness it is best to have a chart of all muscles or muscle groups. The paralyzed muscles are graded on the chart according to the following key:

Zero = no power

Trace = slight ability to contract a muscle

Poor = ability of the muscle to move the affected part through its normal arc with gravity eliminated

Fair = power to function against gravity

Good = power to function against gravity plus resistance

Normal = normal function

A record of this type enables one to see at a glance what the physiologic problem is and helps one to meet it intelligently.

Systematic exercises are now prescribed for the affected muscles in order to improve their function. The paralyzed parts must be supported in such a way as to avoid any drag on weakened muscles and to prevent

Early walking must not be allowed unless it is obvious that there will be no return of power and a patient with a severe case practically never should be allowed to walk during the first year unless his morale is being affected by too much rest. Swimming and

Fig. 961.—Opponens pollicis paralysis in poliomyelitis (Children's Hospital case)

exercises in water tanks are very helpful for those who are extensively paralyzed. Massage and the application of heat are of assistance in promoting the circulation and should precede the more active forms of physiotherapy. Electricity has been extensively used but without much success, the principal objection to its use being the inability to measure the dose. It is not a passive form of therapy.

Chronic Stage—There is no sharp border line between the convalescent and the chronic stage. The chronic stage is that of residual paralysis, deformities and disturbances in locomotion.

Locomotion—A great deal may be learned about the disabilities due to the paralysis by having the patient walk. The type of limp, the deformity and the consequent loss of function may be readily observed.

Deformities—Feet—Equinus, foot drop, valgus, varus or calcaneus and combinations of two or more of these.

Knees—Flexion, hyperextension, varus and valgus.

Hips—Dislocation, abduction, adduction, flexion and rotation. In addition to these conditions there may be shortening and twisting of the leg.

Fig. 962.—Deltoid paralysis in poliomyelitis (Children's Hospital case)

contractures. It is well known that a weak unsupported muscle will steadily lose in power if overused or not protected. Deformities must be guarded against during this stage by suitable apparatus and meticulous attention to posture.

Spine—Scoliosis

Shoulders—Adduction of the shoulders
subluxation and prominent scapulae

Elbows—Flexion pronation and supination

Wrists—Flexion extension adduction and abduction

Fingers—Extension and flexion

Thumbs—Extension and external rotation

These deformities may be apparent or fixed. If fixed, they are due to bony changes and contracted ligaments, muscles and fasciae. When not fixed they are due to overbalance of muscle power or to faulty weight bearing on improperly supported or unsupported extremities. Correctible deformities must be treated with the proper apparatus. Non correctible deformities are treated by stretching in plasters or splints or by operations.

Treatment During the Chronic Stage—1. *Muscle re-education* must be carried on just so long as there is any indication of improvement and also after operations.

2. *Apparatus*—Braces, plaster casts and splints are used to aid the patient in walking and also in correcting deformities after they have occurred.

3. *Operations*—(a) Operations to improve function are lengthening of tendons and fasciae, and tendon transplantations. (b) Operations to improve stability are tenodesis, astragalotomy, arthrodesis and proximal arthrodesis.

Simple equinus can be corrected and not a liability, since its mechanical action assists in locking a paralyzed knee joint thereby permitting the patient to walk without a long brace. In many instances it is necessary to relieve a permanent equinus by the application of plaster from the toes to the knee. Straps and buckles are incorporated in the plaster when it is being applied and an orange-peel section is removed from the dorsal aspect of the ankle. Gradual tightening of the straps will often relieve the equinus. In cases of persistent equinus it may be necessary to lengthen the tendo achillis; this should always be by open operation. The tendon is divided by a long oblique or Z type of incision and carefully sutured after the condition is corrected.

Subcutaneous tenotomies may fail to unite

and may result in flat foot or a bad calcaneus.

Tendon transplantation has a wide application in both extremities. The following are the main requirements for successful tendon transplantation.

1. Rigid asepsis
2. Selection of a suitable case
3. Sufficient power in the transplant to secure good function
4. A minimum amount of handling of the tendon
5. The direction of the transplant to be as nearly as possible in line with the muscle it is to replace
6. The carrying of the transplant beneath the deep fascia when possible
7. Bone insertion (this is desirable in the lower extremity)
8. Removal of a fixed deformity by a primary operation or at the same sitting
9. Transplantation of tendons under moderate tension
10. Heavy silk to be used for the insertion (this is the most dependable material)
11. Attention to leverage (this is important)
12. Overcorrection of the deformity

In children over seven years of age transplantations in the foot are more satisfactory when combined with some stabilizing operation. However in order to avoid severe deformity, it may be wise to transplant early and delay the stabilizing procedure until the bones are less cartilaginous in structure.

Operations to Improve Stability.—*Tenodesis* was originated by Codivilla and later improved by Gallie. It is more successful in adults with foot drop, valgus or varus. It consists in suturing the distal end of a divided tendon or tendons to the bone proximal to the deformity.

Astragalectomy. Whitman's operation is indicated in flail feet and in severe calcaneus but has been largely superseded by arthrodesis.

Arthrodesis is designed to secure stability with a minimum loss of motion (Hoke and Ryerson). It is best combined with tendon transplantation when possible since the stabilizing factor permits the transplanted tendon to function more strongly in its new position. This operation has been refined so that it is applicable in flail foot, equinus and calcaneus deformities (Brewster advocates countersinking the astragalus). Campbell a posterior bone block for equinus and Putti an anterior bone block for calcaneus.

Pan arthrodesis is reserved for flail feet. The astragalus is arthrodesed in the tibia, calcaneus and navicular bones.

KNEE—*Flexion* of the knee is due to contracture of the hamstrings and may be corrected by the application of a plaster cylinder extending from the ankle to the groin. This is divided posteriorly leaving a short isthmus of uncut plaster over the patella. From day to day wedges are inserted at the back of the plaster until the knee is straight.

Knock knee may be corrected manually under an anesthetic if the bones are atrophied. The fracture usually takes place just below the tibial tuberosities and is incomplete without displacement of the fragments. If the bone is hard it will be necessary to divide it with an osteotome just below the head of the tibia. The deformity is overcorrected and the fractured ends are impacted. Performing an osteotomy below the joint instead of above allows the surgeon to apply a leg cast instead of a spica.

Hyperextension is due to weakness of the hamstrings or of the gastrocnemius muscle or to permanent equinus. This may be relieved by attention to the equinus if present and by tenodesis of the tibial head of the biceps tendon to the femur. The inner hamstrings also may be used.

Tendon Transplantation of the Knee—This operation is indicated in palsy of the extensors or flexors. To relieve a paralyzed quadriceps the biceps femoris is often used; also the sartorius and the tibial band singly or in combination. The insertion is made on the bare surface of the patella and the tendons are sutured to the ligamentum patellae and the aponeurosis. If there is weakness of the hamstrings the tibial band may be transplanted posteriorly into the split biceps tendon and the posterior aspect of the tibia.

Hip—*Flexion* is the most common deformity. It may be relieved by Sontter's operation which consists in dividing the fascia lata opposite the anterior superior

spine laterally and stripping the muscular attachments from the anterior, lateral and medial aspects of the front of the iliac crest, anterior superior spine and interspinous notch. Young advocates division of the tibial band just above the patella.

In an early case the deformity may be stretched gradually by the use of a raised frame and casts applied to the leg allowing the weight of the legs to stretch out the contractures. Associated with a flexion deformity there is often weakness of the gluteus maximus and sometimes if location occurs. The tibial band may be stripped upward and the lower end transplanted to the erector spinae muscles. If the acetabular shelf is too shallow to hold the femoral head a new shelf may be constructed.

Abduction Paralysis—Legg's operation is valuable for this condition. It consists in transplanting the freed origin of the tensor fasciae latae backward so that it will act as an abductor.

Deformities of the Upper Extremities—For the relief of paralysis of the deltoid muscle arthrodesis and tendon transplantations are useful but these procedures are of no value if there is no function in the hand and elbow.

In arthrodesis the humeral head is fused to the glenoid cavity. This operation is more successful when the tip of the acromion is fused to the humerus. The arm is placed in a spica in 70 degrees of abduction and the elbow just forward of the coronal plane. Bamford, Sontter, Lange, Mayer and others have used the upper trapezius to relieve the paralyzed deltoid muscle with more or less success.

Transplantation of the short head of the biceps and the long head of the triceps to the acromion when there is good or normal power gives excellent results. When these muscles are weak the trapezius operation may be combined with the biceps and triceps transplants.

Elbow—*Flexor weakness* at this joint may be improved by transplanting the forearm muscles on the inner condyle 2 inches upward. This may be combined with a similar procedure on the lateral condyle (Steindler).

Triceps paralysis may be relieved by transplanting a normal brachioradialis posteriorly. This may be done without division of the muscle.

Wrist and Fingers—The flexor carpi ulnaris may be transplanted to the extensor of the fingers to relieve extensor weakness.

Paralysis of the opponens pollicis is helped by Ney's operation and by Russell's operation or by a modified combination of the two (author's method) which is as follows: The extensor brevis pollicis is isolated as in the Ney operation and then the flexor sublimis digitorum of the ring finger above the wrist and divided. The first muscle is passed deep across the palm of the hand behind the finger flexors and the extensor brevis is sutured to the proximal portion of the finger flexor. The distal portion of the flexor is sutured to the flexor of the fifth finger.

Wrist drop may be corrected by fusion of the radius to the carpus or tenodesis of the wrist extensors.

Spine—*Lateral curvature of the spine* is due to paralysis of the spinal abdominal or shoulder muscles. It may be due to a short leg or a contracted iliac band.

The function of the foot and ankle is twofold weight bearing and flexible locomotion. The normal weight bearing line is represented by a plumb line dropped from the middle of the patella. It falls through the middle of the astragalus and touches a point between the bases of the first and second toes.

Flatfoot—Flatfoot may be either congenital or acquired. Heredity is undoubtedly an important factor. A type of flatfoot appears during adolescence in long slender rapidly growing feet especially in girls.

NORMAL INNER SIDE OF FOOT

Fig 267—Showing what occurs in case of a depressed longitudinal arch

Focal infection or any infectious disease can cause flatfoot by a toxic relaxation of the supporting structures. These infections may cause toxic arthritis and a rigid valgus deformity which is resistant to treatment. Obesity causes flatfoot in two ways: first by the strain of an excessive load when there is usually a disproportion between the weight to be carried and the size and power of the feet and lower part of the legs; second by the glandular imbalance which is found in conditions such as dystrophia adiposa.

Metatarsalgia means pain in the metatarsal region. Metatarsal troubles are more common in women because of the wearing of improper and incorrectly fitted shoes. Short or tight stockings are additional factors. Arthritis may cause metatarsalgia. Infections may be local or focal, such as those due to infected teeth, tonsils, sinuses or abdominal or pelvic structures. Toxemia from an infection or from pregnancy is a causative factor. Static disturbances such as prolonged standing on hard floors and improper

Fig 268—Bones of the foot (top view) in normal and flatfoot positions

genitals in which there is genu valgum and talipes valgus due to relaxation of the supporting structures of the inner border of the knee and foot. Trauma may result in a pronated foot. Infantile paralysis is a frequent cause of valgus deformity.

The symptoms of flatfoot are fatigue, pain and stiffness. The gait is springless and ungraceful.

Physical examination reveals pronation of the midtarsal area with abduction of the forefoot. Heiberg's sign is an incurving of the achilles tendon (Fig 266 B).

sitting postures resting on the toes predispose to metatarsal disturbances. Traumas of various sorts are important, viz. strain or sprain as seen in the dancer's foot, especially in toe dancing. Injury from falling objects or from being stepped on by another person or animal may cause metatarsalgia.

Treatment of metatarsalgia consists of local and general measures, the latter being the removal of foci of infection and the correction of metabolic and hygienic disturbances. Local treatment consists of relief from inflammation or irritation, proper shoes that

Fig 269.—Various types of shoe modifications or adjustments. Fig 270.—A, Normal position of metatarsal heads and sesamoid bones. B, depressed metatarsal arch. C, depression of fourth metatarsal head, with predisposition to callousity.

are correctly fitted, metatarsal support and the physiologic restoration of the power of the supporting structures of the arch.

McElvenny finds that Morton's toe is caused by a tumor involving the lateral branch of the medial plantar nerve. Careful palpation will usually reveal the tumor, which lies high in the web between the third and fourth toes. He advises excision of the tumor when the symptoms justify radical treatment.

Pes cavus is a hollow or contracted foot. The primary change is an exaggeration of the longitudinal arch. The secondary changes consist of limitation of dorsal flexion of the ankle joint and depression of the metatarsal arch with contractures of the plantar fascia and extensor tendons. Calluses and ulcers may appear.

Bunion is bursitis in the region of the big toe joint.

Hallux valgus is the outward deviation of the big toe with the formation of an overgrowth of bone (exostosis) at the big toe joint (Fig. 271). The chief causes are short or pointed shoes and injury. The most im-

* Lewin: *The Foot and Ankle*, Lea & Febiger, Publishers.

portant prophylactic measure is the wearing of proper shoes. The McBride operation (Fig. 272) is useful

Hallux varus means the inward curving of the big toe.

Metatarsus varus means adduction of the forefoot.

Hallux rigidus means a rigid metatarsophalangeal joint. Both the flexed and the extended variety are due to injury or infection and may be relieved by the insertion of a thin strip of steel the entire length of

affords comfort, but occasionally removal of bone is necessary.

Exostoses of the first metatarsal usually occur on the lateral, medial and superior surfaces of the metatarsal head. The most frequently seen is the one occurring on the medial surface, which is so common in hallux valgus. In simple cases, removal of the exostoses gives complete relief. Exostoses of the fifth metatarsal usually occur on the lateral margin corresponding with those on the medial margin of the first metatarsal head

Fig. 271—Severe bunions and hallux valgus (Note the large plantar calluses in A) *

the sole of the shoe so as to prevent movement at the big toe joint. The condition can be corrected by an arthroplastic operation.

Sesamoiditis is a painful condition involving the under surface of the big toe joint. This surface is subject to trauma in walking, in jumping from a height or in dancing. Often the roentgenogram will reveal a division of a sesamoid bone resembling fracture. Many of these are developmental peculiarities which are especially susceptible to injury. Usually relief from weight bearing

Calcaneal or heel spurs are due to various causes, such as (1) focal infections with the ordinary cocci, gonococci and spirochetes, (2) metabolic disturbances, especially of gastrointestinal and gallbladder origin (large numbers of cases are seen in which the metabolic factor either was most important or was an element in the exaggeration of other factors), (3) trauma due to injury and improper shoes, (4) static conditions due to flatfeet and (5) a short

* Porter, J. L. Surg. Gynec. & Obst. 26

plantar fascia Painful heel may also be due to a wart, periostritis, bursitis, fasciitis, epiphysitis or an injury.

Treatment—The causative factors—the residue of a gonococcus infection, infected

pads are inserted in the shoes to relieve weight bearing on painful areas. The heels of the shoes should be entirely removed and low rubber heels substituted.

The diet is very important in cases of

Fig. 2.—a Incision slightly curved laterally to the tendon of the extensor hallucis longus. b The conjoint tendon of the transversus and oblique leads of the adductor hallucis and the flexor hallucis brevis are exposed and severed from their attachments. The exostosis is exposed through the same incision. c Transplanting the conjoint tendon to the head of the metatarsal. The prominence of the metatarsal head has been removed.*

tonsils or teeth—should be treated if they can be found. Any gastrointestinal disorder present should be corrected. Weight bearing should be discontinued. An anodyne lotion plus fomentations should be applied.

metabolic disturbance. As a rule in heavy patients meat, eggs, fish, starches and sweets should be reduced. Diathermy or inductothermy may be beneficial for an accompanying arthritis.

Fig. 3.—Well-developed calcified spur causing no symptoms.

After all pain and most of the sensitiveness have disappeared a plaster of paris cast should be applied. Proper shoes are prescribed after from two to four weeks of wearing casts. Shoes should be high laced and round toed with a straight last, a medium width shank and a medium heel at first. Felt

Operative Treatment—Operative trauma often stimulates osteogenesis especially if the infectious or causative agent is still present. The size of the spur is not the determining factor. The incision should be made along the inner border of the heel. The re-

* McBride, F. D. J. Bone & Joint Surg. 10.

removal of the spur is accomplished by means of a chisel and mallet. A plaster cast should be worn for about ten days.

Corns and calluses are due to pressure and irritation. Corns are of two varieties: 1. The hard corn which occurs on an external surface and is usually caused by an ill fitting shoe. This readily yields to good chiropody and proper shoes. If not too much irritated a corn may be amenable to home treatment by means of the ordinary corn plaster with a hole in the middle large enough to keep the corn free from further irritation. 2. The soft corn which occurs where two skin surfaces come together: e. g. where there is contact moisture and warmth. This type of corn is usually found between the fourth and fifth toes and is at times quite resistant to treatment. Dermatitis, tinea, and eczema predisposes to soft corns because of the softness of the skin. In the treatment one must have separation of the skin surfaces, radiation of heat and evaporation of perspiration. Lamb's wool worn between the toes is of value. Flexible support for the anterior arch is usually helpful. Calluses are due to inconstant pressure or irritation. Constant pressure produces an ulcer or destruction of tissues. Inconstant pressure produces thickening of tissues or calluses. They are common under the ball of the foot especially back of the third and fourth toes. In this region they are due to depression of the heads of the metatarsal bones which help to make up the transverse arch. The patient feels as if he were walking on marbles or as if the bones were down on the ground and had no padding. This results in irritation of the periosteum covering the bones and occasionally in bursitis in this region. I. H. Ochsner has treated corns, calluses and warts with bichloroacetic acid.

Emery paper is effective in removing the painful factor.

Ingrown toe nail is due to the growth of the edge of the toe nail into the soft tissues. The most important site is the big toe nail where on either its medial or its lateral aspects the nail curves downward causing pressure and irritation of the soft tissue structures. This condition may continue until serious results are produced. The treatment includes the wearing of proper shoes and stockings, the picking of cotton under the nail and the scraping of the midportion of the nail thin in order to relieve pressure from the lateral margins. Most advanced cases require operation which includes removal of the lateral margin of the nail, the nail bed which forms the lateral margin and in some cases portions of the injured soft tissues.

Subungual warts are due to exostoses of the terminal phalanx causing irritation and hypertrophy of the epidermal tissues. *Subungual exostoses* are bony overgrowths which occur under the nail and frequently must be treated surgically.

LIEUTENANT COLONEL PHILIP LEWIS

fore the location of choice for the scar is directly on the end of the stump

Fascia—To preserve the blood supply the fascia should be left attached to the skin flap when possible. To raise the skin and fascia separately damages the blood supply to both. Fascia is the normal envelope of the muscle and should be used to cover the muscle at the end of the stump. It also serves as a good covering for the cut end of bone as well as furnishing suitable tissue to which the cut ends of muscles may acquire a new insertion. When the muscle is properly covered with fascia adhesions cannot form between the muscle and the skin, thus a smooth stump end with movable skin is obtained.

Muscle—To allow for retraction muscles should be cut longer than bone. By grouping the severed muscles about the cut ends of bone new insertions may be required to the bone to each other and to the covering fascia. Careful attention to muscle grouping will prevent protrusion of bone beneath the skin and make a smooth well functioning stump.

Nerves—The most frequent cause of a tender stump is a sensitive neuroma which forms on the nerve end. The patient may complain much of feeling his toes or fingers and often a cramping drawing sensation causes great distress. For a long time he may complain of a phantom limb. Various plastic methods such as turning back and suturing nerve flaps, cutting a wedge from the nerve end and turning the nerve end back and suturing within the nerve sheath have been practiced with little success. Injection of the nerve above the point of section with 95 per cent alcohol as suggested by Huber and Lewis offers the best hope of avoiding the development of tender neuromas. Sectioning the nerves with a cautery, according to Hedri, will cause a degeneration of the nerve fibers upward for a distance of several centimeters. Kirk ligates the nerve high with plain catgut to control bleeding and injects the nerve trunk proximal to the ligation with 95 per cent alcohol. The nerve is then severed just distal to the ligature, allowing it to retract 1 to 2 inches

carefully ligated with catgut. As little tissue about the vessels as possible should be included in the ligatures. Tissue strangulation by ligatures predisposes to sloughing and infection.
